ABSTRACT

The climatic impact of ocean heat transport (OHT) is studied in a series of idealized aquaplanet climate model experiments. OHT is prescribed through a simple geometrical formula spanning a wide variety of amplitudes and meridional extents. Calculations with a comprehensive GCM are compared against a simple diffusive Energy Balance Model (EBM). The GCM response differs from the EBM in several important ways that illustrate linkages between atmospheric dynamics and radiative processes. Increased OHT produces global mean warming at a rate of 2 K per PW OHT across $30°$, and a strong reduction in meridional temperature gradient. The tropics remain nearly isothermal despite locally large imposed ocean heat uptake. The warmer climate features reduced equatorial convection, moister subtropics, reduced cloudiness, and partial but incomplete compensation in atmospheric heat transport. Many of these effects are linked to a weakened Hadley circulation. Both the warming pattern and hydrological changes differ strongly from those driven by CO_2. Similar results are found at $0°$ and $23.45°$ obliquity. It is argued that clouds, rather than clear-sky radiative processes, are principally responsible for the global warming and tropical thermostat effects. Cloud changes produce warming in all cases but the degree of warming depends strongly on the meridional extent of OHT. The strongest warming occurs in response to mid-to-high latitude OHT convergence, which produces widespread loss of boundary layer clouds. Temperature responses to increased OHT are quantitatively reproduced in the EBM by imposing GCM-derived cloud radiative effects as additional forcing.

3

1. Introduction

A fundamental feature of the climate system is the poleward transport of energy to counteract the differential heating of the earth's surface by the sun. This total heat transport (THT) is comprised of atmospheric and oceanic components. In the atmosphere, transient eddies, stationary eddies, and the mean meridional circulation (MMC) all work to transport moist static energy (MSE) poleward, whereas in the ocean, sensible heat is transported out of the tropics via surface and deep ocean currents. Observationally-based estimates show the THT to be remarkably symmetric about the equator, with maxima of roughly 5.5 PW near $35°$ in both hemispheres. The atmospheric heat transport (AHT) component dominates poleward of $30°$ N and S reaching a peak of 5 PW near $43°$ while the oceanic heat transport (OHT) is strongest in the deep tropics, with peaks near 2.1 PW and 1.6 PW at $18°$N and S (Trenberth and Caron 2001; Wunsch 2005; Czaja and Marshall 2006). Unlike the THT, AHT and OHT are not symmetric about the equator, with a slight northward and southward cross-equatorial transport of the oceanic and atmospheric components respectively.

While Held (2001) argued that variations in AHT and OHT are coupled through their Ekman transports, modeling studies have shown that tectonic movement of tropical landmasses can give rise to significant changes in OHT, partly through modulations of the tropical oceanic static stability (i.e., depth of the tropical thermocline) (Bice et al. 2000; Enderton and Marshall 2009; Ferreira et al. 2011). Stone (1978) showed that THT is set by astronomical parameters and albedo, and is largely insensitive to variations in AHT and OHT. This implies that any increase in the OHT must be accompanied by a compensating decrease in the AHT to maintain equilibrium. This compensation has been a constant presence in the modeling community, in both past simplified models (Bjerknes 1964; Manabe 1969), and recent, more advanced coupled General Circulation Models (GCM) (e.g., Yang et al. 2015).

OHT is driven by both tropical shallow wind-driven gyres and overturning cells as well as cross-equatorial deep circulations. These processes vary on numerous different time and spatial scales (Ferrari and Ferreira 2011), ranging all the way up to the longest tectonic timescales, at which OHT is primarily determined by continental boundaries and gateways (e.g Covey and Barron 1988; Bice et al. 2000; Enderton and Marshall 2009; Ferreira et al. 2011). Since most of these timescales are well separated from the rapid equilibration of the atmosphere, it is meaningful to study the climatic impact of OHT variations in uncoupled climate models in which OHT patterns are prescribed.

One of the outstanding problems within the climate community has been how to reconcile the geological proxy records of past warm, equable climates such as the Early Eocene (56-48 Ma), characterized by both an increase in the global-mean surface temperature and a decrease in the equator-to-pole temperature gradient (Greenwood and Wing 1995; Crowley and Zachos 2000), with the numerical simulations of the same period (Barron 1987; Huber and Sloan 2001; Caballero and Langen 2005; Rose and Ferreira 2013). A key feature of these climate states is the presence of a "tropical thermostat" mechanism preventing substantial changes in equatorial sea surface temperature (SST) despite potentially large forcings (Pearson and Palmer 2000).

Previous studies of the climatic impact of OHT variations in uncoupled climate models (Winton 2003; Herweijer et al. 2005; Barreiro et al. 2011; Rose and Ferreira 2013; Koll and Abbot 2013) have consistently found that OHT warms the planet. Increased oceanic energy flux out of the deep tropics results in global mean surface warming and a reduction of the equator-to-pole temperature gradient, indicating the presence of a tropical thermostat mechanism. This warming is remarkable given that a change in OHT represents a conservative forcing that simply redistributes energy between different latitude bands. The lack of local cooling of the deep tropics is also remarkable, given that these are regions of locally enhanced ocean heat uptake. Because OHT is completely

unconstrained by paleoclimate proxy data (Bice et al. 2000), it is possible that variations in OHT are a significant driver of climate change during these periods.

Global mean warming from increased OHT might be expected due to a reduction in sea ice extent and consequent decrease in planetary albedo. The sea ice margin is strongly coupled to convergence of OHT in the subpolar oceans (e.g., Bitz et al. 2005; Rose et al. 2013; Singh et al. 2017). A number of previous modeling studies have indeed found that the global climatic response to OHT variations is mediated at least in part by sea ice feedbacks (Seager et al. 2002; Winton 2003; Herweijer et al. 2005; Barreiro et al. 2011; Singh et al. 2017). This coupling is especially prominent in aquaplanet simulations with interactive sea ice compared to more realistic continental configurations (e.g., Langen and Alexeev 2004; Ferreira et al. 2011; Rose et al. 2013; Rose 2015), perhaps because of the lack of geographic muting effects of high-latitude continents (Eisenman 2010).

On the other hand, many of the above studies attributed substantial warming to radiative feedback processes unrelated to sea ice. Herweijer et al. (2005) varied the amplitude of the present-day OHT pattern in several models, and attributed the largest share of the surface warming to increased clear-sky greenhouse trapping by water vapor. Rose and Ferreira (2013) took a more idealized approach, applying a wide range of magnitudes and meridional patterns of OHT to an intermediate-complexity aquaplanet model in a warm, ice-free regime. They also found warming dominated by clear-sky water vapor effects. Increased upper-tropospheric water vapor in their simulations was attributed to extra-tropical moist convection. Interestingly, the warming extended to the poles in all cases, insensitive to the meridional structure of the OHT. Koll and Abbot (2013) used similar idealized experiments (but more comprehensive models, though also ice-free) to study the tropical thermostat mechanisms preventing substantial changes in equatorial sea surface temperature

6

(SST) in response to changes in OHT. They found that both decreased wind-driven evaporation and equatorial convection associated with the slowdown of the Hadley cell played a major role.

The idealized study by Rose and Ferreira (2013) was motivated by coupled simulations showing that meridional profiles of OHT are not fixed, but can vary with continental configuration and climatic state (e.g., Hotinski and Toggweiler 2003; Enderton and Marshall 2009; Ferreira et al. 2010, 2011; Rose 2015), as different modes of ocean circulation are emphasized. The purpose of this paper is to extend the work of Rose and Ferreira (2013) to a more comprehensive climate model. We will apply the same broad range of OHT patterns and magnitudes in an aquaplanet model with substantially higher vertical resolution and less idealized parameterizations of the moist physics. The aquaplanet allows us to better unravel the mechanisms driving the climate change without the complicating effects of land-sea interactions. Such models have been shown to be surprisingly earth-like in nature (Medeiros and Stevens 2011) and a crucial step in the model hierarchy framework needed to fully understand the climate system (e.g. Held 2005; Jeevanjee et al. 2017).

To this end, we adopt the simple formula of Rose and Ferreira (2013):

$$\text{OHT} = \Psi \sin(\phi) \cos(\phi)^{2N} = \Psi x (1 - x^2)^N \tag{1}$$

where $x = \sin(\phi)$, ϕ is latitude, N is a positive integer that sets the meridional extent of OHT, and Ψ is a constant (in units watts). N ranges from 1 to 8, as shown in Fig. 1a. Ψ is chosen to give maximum amplitudes ranging from 1 to 4 PW in our simulations. This range is deliberately chosen to more than span the entire plausible range of OHT on Earth, as captured by observations (Trenberth and Caron 2001) and coupled simulations with different continental configurations and background states (Ferreira et al. 2010; Hotinski and Toggweiler 2003; Rose 2015).

Taking the convergence of (1) (see (A5) in appendix A1) gives the q-flux prescribed in the ocean mixed layer, plotted in Fig. 1b. There is a steady surface heat sink straddling the equator, and an

7

equal-but-opposite heat source in the subtropics (for large N) or mid- to high latitudes (for small N). The global mean forcing is 0 W m^{-2} in all cases. The forcing is zero at the poles in most cases. The exception is $N = 1$, where maximum OHT convergence occurs at the poles. This polar-amplified heating pattern will turn out to be an outlier in our set of simulation results. Such a wide range of OHT patterns has yet to be studied at this level of the climate model hierarchy.

Before introducing our GCM simulations, it is useful to define a baseline climatic response to a 1 PW increase in OHT using a very simple energy balance model (EBM). The EBM is a one-dimensional diffusive model based on the zonal-mean perturbation energy budget:

$$C\frac{\partial T}{\partial t} = \lambda T(\phi) + H(\phi) - \nabla \cdot F(\phi) \tag{2}$$

where T is a local SST anomaly, C is a column heat capacity, $\lambda < 0$ is a climate feedback parameter, $H(\phi)$ is the prescribed OHT convergence from (1), and $-\nabla \cdot F(\phi)$ is the AHT convergence (both in W m^{-2}). For our baseline model we adopt the classical dry-diffusive parameterization (e.g. North 1975a), which crucially endows the EBM with a non-local response to the imposed forcing. Details and parameter values are discussed in section 4. The steady-state form of (2) forced by the convergence of (1) is analytically solvable for any N, as laid out in appendix A1.

Fig. 1c shows SST anomalies for a 1 PW increase in OHT in the EBM. This baseline model makes several specific predictions. Global mean warming is zero as expected, given the linear nature of the EBM. The equator cools by nearly 2 degrees. This cooling decreases weakly with N – it scales not with the local equatorial heat sink but rather its cross-tropical average (i.e. with OHT across $30°$ latitude). The extra-tropics get warmer, with maximum warming collocated with maximum heating. Polar warming is a strongly decreasing function of N – it is largest for $N = 1$. The tropical cooling in particular is contrary to the numerous GCM studies discussed above.

Understanding why and how GCMs differ from this baseline is a crucial step toward understanding the role of OHT in the climate system.

Key questions to be addressed here are as follows. How does the GCM response to an increase in OHT differ from the baseline EBM? How robust is the warming effect of increased OHT across a broad range of specified, idealized OHT patterns, and do the mechanisms driving this warming depend sensitively on the spatial pattern on the OHT? What are the relative contributions of cloud versus clear-sky processes to the warming? Specifically, does the equatorial thermostat described by Koll and Abbot (2013) operate for both subtropical-scale and hemispheric-scale OHT variations? We investigate the robustness of our findings to different background climates by repeating our calculations at $0°$ and $23.45°$ obliquity. As we will show, the obliquity itself plays an key role in the equator-to-pole SST gradient, a result that has not been widely appreciated in the literature.

The rest of this paper is organized as follows. Section 2 describes the two configurations of our GCM. The main results are presented in Section 3, including the effects of OHT on temperatures, hydrological cycle, atmospheric circulation, and energy budgets, and a brief aside on the effects of obliquity. In section 4, we use several variants of the EBM to understand the relative importance of different warming mechanisms. Discussions and conclusions follow in section 5.

2. Model Description

We use an atmospheric GCM coupled to an aquaplanet mixed layer ocean with a steady, zonally symmetric prescribed heat source/sink term (the "q-flux") representing regions of convergence and divergence of OHT, as shown in Fig. 1. The model is the Community Atmospheric Model, version 4 (CAM4), with a finite-volume dynamical core at $2.0° \times 2.5°$ horizontal resolution, 26 vertical levels, and a modified form of the Zhang-McFarlane deep convection scheme (Zhang and McFarlane 1995; Neale et al. 2013). The model has fully interactive clouds and water vapor, and

9

thus incorporates many of the fundamental radiative feedback processes. Reference greenhouse gases are 348 ppmv CO_2, 1650 ppbv CH_4, and 306 ppbv N_2O with all other greenhouse gases set to zero. Ozone is prescribed as in Blackburn and Hoskins (2013). The surface albedo is fixed at 0.1. Sea ice is omitted and SST is permitted to drop below freezing. These specifications follow previous aquaplanet intercomparison protocols (Lee et al. 2008; Rose et al. 2014; Voigt et al. 2016).

We choose to exclude sea ice from these simulations because, as mentioned in the introduction, previous studies have shown that the coupling between sea ice and OHT convergence patterns is extraordinarily strong in aquaplanet simulations (e.g., Rose 2015). We wish to study the effects of OHT on atmospheric radiative and dynamical processes without the confounding effect of very large changes in sea ice extent.

We use two different control simulations, both with the q-flux set to zero, but with obliquity set to $0°$ or $23.45°$. The $0°$ or perpetual equinox model has a 10 m mixed-layer depth and is identical to the multi-model comparison analyzed in Rose et al. (2014) and Rose and Rencurrel (2016). The $23.45°$ obliquity model has seasonally varying insolation and a mixed-layer depth of 60 m, designed to replicate the setup used in Rose and Ferreira (2013). $0°$ simulations were run for 30 years, with averages computed over the last 20. $23.45°$ simulations were run for 60 years to account for longer equilibration times associated with the increased mixed-layer depth.

SST profiles for the two zero q-flux control simulations are shown as black lines in Fig. 2. Global mean temperatures are 288.57 K and 291.70 K respectively for $0°$ and $23.45°$ obliquity. The majority of the temperature difference is in the polar regions, as the $0°$ model has zero insolation at the poles and SST is allowed to drop below freezing. We will return briefly to these obliquity-induced temperature differences below in section 3b.

10

3. Results

a. Surface Temperature

Increasing OHT out of the tropics results in a global mean warming and a reduced equator-to-pole SST gradient in all cases. Fig. 2 shows a representative subset of the results for $N = 1$, 2 and 6. Like previous results (Rose and Ferreira 2013; Koll and Abbot 2013; Herweijer et al. 2005), these increases are characterized by nearly invariant equatorial SSTs, extratropical SSTs that depend strongly on the pattern of OHT convergence. This is different than the EBM calculations shown in Fig. 1c which were characterized by a tropical cooling. Fig. 2 also shows the effects of doubling CO_2, which warms at all latitudes in a weakly polar-amplified pattern resulting in a global mean warming of 1.71 and 1.97 K for $0°$ and $23.45°$ obliquity respectively.

The lack of tropical cooling in response to a locally large oceanic energy sink is remarkable. In fact equatorial SSTs actually warm upwards of 2 K in response to large increases in OHT. This, along with the baseline EBM results, implies that the climate system adjusts to the increased OHT by moving energy back into the tropics. Understanding what drives this "tropical thermostat" is key to understanding why OHT warms the planet. Away from the equator, maximum surface warming is usually collocated with the maximum surface heating. The warming extends to the poles only for $N = 1$ (for which the poles are directly heated) and $N = 2$ (peak heating near $50°$ latitude). This differs from Rose and Ferreira (2013), who found polar-amplifed SST responses for all N in their intermediate-complexity model.

We can collapse our two-dimensional array of simulations onto a single axis by plotting global mean SST anomalies versus OHT across $30°$ latitude, as shown in the upper panels of Fig. 3. With the exception of $N = 1$, the results fall onto a single line with a slope of roughly $2\,\mathrm{K\,PW^{-1}}$. That is, a 1 PW increase of the OHT out of the tropics results in a global mean warming of 2 K, regardless

11

of the detailed spatial pattern of the OHT convergence (slightly more at 23.45° obliquity than at 0°). The sensitivity is substantially higher for $N = 1$, in which the polar sea surface is directly heated. As mentioned previously, the sensitivity to doubled CO_2 is 1.71 and 1.97 K for 0° and 23.45° obliquity respectively. Globally, a 1 PW increase in OHT is roughly equivalent to doubling CO_2. However, the warming mechanisms are completely different, as we will show.

The lower panels of Fig. 3 illustrate the dependence of warming patterns on spatial structure of OHT. The contoured quantity is the SST anomaly for a 1 PW increase in OHT from 1 to 2 PW, with latitude on the x-axis and the meridional scale parameter N on the y-axis (and linear interpolation between simulations). The solid black lines show the location of the peak heating, which lies at lower latitudes for larger N. The dashed line at the equator represents the peak energy sink. We refer to this as a "spatial anomaly plot" and use this graphical convention repeatedly hereafter.

Fig. 3 emphasizes that the warming maximum is collocated with the latitude of OHT convergence, and that this warming increases monotonically as the convergence (i.e. the heating) shifts poleward. In the deep tropics, changes are minimal regardless of the spatial pattern of the forcing. This implies a universal response to increased OHT in the deep tropics and a spatially-dependent response in the midlatitudes. We will look into possible mechanisms in the next section.

We found that the changes in SST, as well as the mechanisms driving them, are largely insensitive to the magnitude of the prescribed OHT. For brevity, we will only analyze the anomalies for the most realistic case, an increase in OHT magnitude from 1 to 2 PW. Our conclusions will hold for the other prescribed transport patterns.

b. Effects of Obliquity

As a quick aside, it is worth mentioning the similarities in the warming patterns associated with obliquity and OHT. Increased obliquity from 0° to 23.45° also elicits a global mean warming and

12

a decrease in the equator-to-pole temperature gradient, shown in Fig. 4. This figure also shows the inferred energy transport associated with both the change in annual-mean insolation and surface shortwave flux.

Increased obliquity shifts energy from the tropics to the high latitudes, qualitatively similar to an increase in OHT. Looking first at the prescribed TOA forcing, the inferred insolation transport in Fig. 4 is similar to our 2 PW, $N = 1$ OHT pattern, although the obliquity-induced warming (3.13 K) is only about half as large. This muted response can be attributed to the reflective nature of optically thick clouds. Taking into account the local albedo, we find that the inferred energy transport associated with the SW flux reaching the surface is about half of that of the insolation, better matching the global mean warming.

With that said, and excluding the outlying $N = 1$ case, we have found very little difference in climatic response to OHT variations at $0°$ and $23.45°$ obliquity. Just as with the variations in the magnitude of OHT, we will only present results from the $0°$ simulations hereafter. Our conclusions will hold for $23.45°$ obliquity.

c. Evaporation and hydrological cycle

Fig. 5 shows hydrological cycle changes associated with increased OHT. The drying out of the equator and the moistening of the subtropics are opposite to the "wet gets wetter, dry gets dryer" paradigm for a doubling of CO_2 (Held and Soden 2006), emphasizing the difference between the two warming mechanisms. Net subtropical evaporation ($E - P$) *decreases* with OHT-driven global warming on the order of -7 cm yr^{-1}K^{-1} (-0.2 mm day^{-1} K^{-1}). This is qualitatively similar to the findings of Rose and Ferreira (2013), but about half the rate.

In the absence of other factors such as changes in near-surface relative humidity and the surface-atmosphere temperature difference, evaporation should increase with SST at the Clausius-

13

Clapeyron (CC) rate of roughly 7% K^{-1}. This helps explain the band of increased evaporation collocated with the maximum warming and OHT convergence. However Fig. 5 also shows robust bands of decreased evaporation straddling the equator for all N, which must deviate from the CC rate given the lack of cooling at these locations. Understanding what is driving these evaporative changes may provide insight into the tropical thermostat mechanism.

Following the method of Lorenz et al. (2010), we decompose the fractional rates of change of evaporation into additive contributions from various physical processes represented in the bulk formula for surface evaporation (details in appendix A2). Fig. 6 shows this breakdown for both a doubled CO_2 scenario and an increase in OHT from 1 to 2 PW with $N = 4$. Solid black lines show total deviations from the CC rate (sum of the colored solid lines). Red lines show contributions from air-sea temperature difference (evaporation will increase if SST warms faster than the near-surface air temperature). Blue lines show the relative humidity (RH) contribution (evaporation rates decrease in response to increased boundary-layer RH). Purple lines show contributions from changes in the turbulent exchange coefficients, with the component directly attributable to surface wind speed changes shown in dashed purple.

The doubled CO_2 scenario shows a fairly uniform -5% K^{-1} deviation from the CC-rate, with all three terms contributing to this reduction. This is consistent with the expectation of about 2% K^{-1} increase in evaporation under CO_2-driven warming (Held and Soden 2006). Results for increased OHT are completely different. Across the deep tropics the change is near -25% K^{-1} below the CC rate (yielding an absolute rate of change of about -10 to -20 % K^{-1}). Our decomposition identifies reduced near-surface wind speed as the key factor in this large reduction in evaporation, with second-order and partially canceling contributions from increased air-sea temperature difference and increased RH. As we will show below, the slower wind speeds are a manifestation of a

14

slowdown in the overturning rate of the Hadley cells (HC). In the midlatitudes, deviations from the CC-rate are much smaller and of similar order to the changes under doubled CO_2.

Though we have only plotted a single OHT pattern in Fig. 6 ($N = 4$), the results are relatively robust across all our simulations. Increased OHT causes a substantial reduction in the surface evaporation (and thus of the surface cooling through the latent heat flux, LHF) across the deep tropics, associated with a slowdown of the surface winds. This is a possible mechanism for the tropical thermostat, in agreement with Koll and Abbot (2013).

Returning to fig. 5, the largest hydrological changes are for precipitation: strong reduction at the equator and increases off the equator. These are also associated with a slowdown of the HC, with reduced equatorial convection and subtropical subsidence. Increased convection on either side of the equator is magnified by surface warming associated with OHT convergence for high N. In agreement with Rose and Ferreira (2013), there is also a shift from large-scale, stratiform to convective precipitation in the storm track regions for low N (not shown).

d. Atmospheric Compensation

The hydrological cycle changes shown in Fig. 5 and 6 indicate that large-scale tropical circulation changes play a role in setting the SST response to increased OHT. These same circulation changes may also impact poleward heat transport. Fig. 7 shows the total (THT), atmospheric (AHT), and oceanic (OHT) transport for all simulations. While increasing OHT out of the tropics does result in a compensating decrease in AHT, this compensation is incomplete as THT does increase slightly (up to 1 PW). Despite this, latitudinal shifts in the peak of the THT are nonexistent despite variations in the spatial pattern of the forcing. This is in line with Stone (1978), which predicted the presence of a transport peak near $35.3°$ that is also insensitive to partitioning changes. It is also worth noting that in some of the more extreme cases, AHT reverses and moves energy

15

equatorward. We find that these states are characterized by a prominent double ITCZ, resulting in secondary circulation features in the upper troposphere transporting dry static energy equatorward.

To better understand how this partial compensation is accomplished, we decompose AHT into changes associated with the mean meridional circulation (MMC) and the transient eddy component (Trenberth and Stepaniak 2003; Hill et al. 2015). AHT is calculated as

$$F_{tot}(\phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\phi} \left(\left[\overline{Q}_{TOA} \right] - \left[\overline{Q}_{sfc} \right] \right) \cos \phi \, d\phi \tag{3}$$

with Q_{TOA} and Q_{sfc} the downward energy flux at the TOA and surface, a the planetary radius, and the square brackets and overbars representing zonal and time mean respectively. The MMC component of this flux is calculated as

$$F_{HC}(\phi) = 2\pi a \cos \phi \int_{P_{top}}^{P_{sfc}} \left[\overline{m} \right] \left[\overline{v} \right]_{adj} \frac{dp}{g} \tag{4}$$

with m the moist static energy (MSE), v_{adj} the meridional wind adjusted for mass imbalance over the entire column following Hill et al. (2015), P_{top} and P_{sfc} as the pressure at the tropopause and surface respectively. Because stationary eddies are negligible on a zonally symmetric aquaplanet, the transient eddy component is simply taken to be the residual between (3) and (4).

Results are plotted in Fig. 8. The AHT adjustment is largely a local response to OHT variations, in the sense that changes in AHT tend to be equal and opposite to changes in OHT and thus occur farther poleward for small N. The primary mechanism for this compensation shifts from MMC for large N to transient eddies for small N. This is perhaps not surprising, as the HC and transient eddies are largely tropical and midlatitude phenomenons respectively. However the tropical decrease in the MMC component is robust for all N.

In the tropics, then, the majority of the AHT decrease can be attributed to changes in the HC. This is partially accomplished through the physical slowdown of the cell, which can be measured through its mass flux. We compute ψ_{max}, the signed maximum of the Eulerian meridional mass

16

streamfunction (Ψ), from

$$\psi(\phi, p) = 2\pi a \cos\phi \int_0^p [\bar{v}]_{adj} \frac{dp}{g} \tag{5}$$

Fig. 8 shows a decrease in the mass flux for all N. This implies that an increase in OHT, regardless of its detailed spatial structure, results in a compensating decrease in the AHT partially achieved by a slowdown in the HC. It is important to note that this slowdown is robust across all N, implying that many of the conclusions regarding the climatic impacts of the HC slowdown in past works (Koll and Abbot 2013) as well as below are also robust to the spatial structure of OHT. We will analyze the dynamical and thermodynamical mechanisms driving this robust HC slowdown in future work.

e. TOA energy budget and clouds

Increasing OHT out of the tropics results in a compensating decrease in AHT, partially accomplished through the slowdown of the HC. But how do these circulation changes contribute to weaker equator-to-pole temperature gradients, and what, if anything, is amplifying the warming at mid- to high latitudes? Here we examine aspects of the energy budgets at TOA and the surface to gain some insight into these questions.

Fig. 9 shows changes in TOA radiative fluxes along with the surface LHF. There is a net TOA energy flux into the tropics and out of the midlatitudes for increased OHT, amplified in the polar regions. This increased meridional gradient is associated with the slightly increased THT found in all runs. There are large, partially compensating changes in TOA longwave (LW) and short-wave (SW) radiation budgets at the equator across all N, resulting in the net energy flux into the climate system. On either side of the equator there is a slight increase in the LW flux. These compensating changes are also present in the midlatitudes, amplified in the storm track regions for low N. The polar regions are characterized by a decrease in both the LW and SW energy fluxes,

17

resulting in the net deficit. The LW anomalies result from a combination of cloud and clear-sky greenhouse trapping changes. The SW anomalies, on the other hand, are almost entirely dictated by cloud changes since the surface albedo is fixed in our ice-free aquaplanet simulations. These SW changes are nearly universally positive across our ensemble of simulations, indicating a robust loss of clouds in response to increased OHT. Changes in the surface LHF mirror the evaporation anomalies from Fig. 6.

Fig. 10 shows cloud fraction changes, decomposed into high, mid- and low cloud. Equatorial cloud cover decreases at all levels in all cases, a consequence of the weakening HC and reduced equatorial convection. Away from the equator, the largest changes are found in the low clouds. In the subtropics, reduced subsidence associated with HC slowdown results in near-uniform re-duction of low clouds for all N. In the midlatitudes, the dominant effect appears to be decreased lower-tropospheric stability associated with the sea surface heating for small N, which tends to eliminate the stable inversions that sustain low cloud cover (Wood and Bretherton 2006). For high N, the destabilizing effect of subtropical surface warming invigorates local convection, driving the increase in mid and high clouds. Results for the polar region are mixed, with decreased low clouds for all but the $N = 1$ case. Overall, Fig. 10 shows that global cloudiness decreases with increased OHT, and the effects are largest for small N (large-scale OHT). The climatic impacts of these cloud changes will be quantified in the next section.

The increased LW flux to space shown in Fig. 9 is consistent with the warming climate but also includes effects of any changes in greenhouse trapping (e.g. by water vapor or clouds) that may be causing the warming. To help disentangle these, in Fig. 11 we plot changes in greenhouse trapping, defined as the difference between surface emissions and emissions to space:

$$G_t = \varepsilon_s \sigma T_s^4 - OLR \tag{6}$$

18

where σ is the Stefan-Boltzmann constant and $\varepsilon_s = 0.98$ is the surface emissivity prescribed in the GCM. Positive ΔG_t indicates an enhanced greenhouse effect that contributes to the surface warming. We decompose ΔG_t into additive clear-sky and cloudy-sky changes $\Delta G_t^{clear}, \Delta G_t^{cloudy}$ as detailed in appendix A3. Importantly, our clear-sky trapping diagnostic ΔG_t^{clear} is *not* simply (6) computed with the clear-sky LW flux; rather it is reduced by the climatological clear-sky fraction at each location, so that it represents actual contributions of clear-sky processes to changes in trapping (see appendix).

From Fig. 11, ΔG_t decreases slightly at the equator and an increase pretty much everywhere else, with the maximum collocated with the latitude of OHT convergence, and amplified in the polar regions for low N. ΔG_t^{clear} is small but positive across broad swaths of the subtropics and mid-latitudes, indicating a moistening of the atmosphere with warming. ΔG_t^{cloudy} is negative (decreased trapping) at the equator but positive everywhere else, and typically larger than ΔG_t^{clear}. This is especially true for small N, for which the changes at mid-to-high latitudes are very large. Thus changes in the greenhouse effect of high latitude clouds are playing a strong role in the polar-amplified warming for small N, while clear-sky greenhouse processes are secondary and not as dependent on the spatial structure of OHT.

4. Diffusive model interpretation

Results in the previous section strongly suggest that cloud changes play a dominant role in driving the global warming in response to increased OHT. In this section we return to the simple EBM introduced in section 1 with the specific goal of understanding the relative importance of clear-sky feedbacks and cloud changes on the warming patterns.

19

We extend (2) with an additional radiative forcing term $R(\phi)$ on the RHS representing cloud forcing, and we also allow the clear-sky feedback λ to vary with latitude:

$$C\frac{\partial T}{\partial t} = \lambda(\phi)T(\phi) + H(\phi) + R(\phi) - \nabla \cdot F(\phi) \qquad (7)$$

The feedback $\lambda(\phi)$ is the sum of the Planck, lapse rate and water vapor feedbacks, which we calculate by the radiative kernel method (Soden et al. 2008). We use radiative kernels for a zonally symmetric aquaplanet from Feldl and Roe (2013).

We treat the GCM-derived cloud response as an external forcing $R(\phi)$ in the EBM. Specifically we set $R(\phi)$ equal to the anomalous Cloud Radiative Effect (CRE) associated with a given increase in OHT, where CRE is the difference between all-sky and clear-sky TOA radiative flux. This allows us to isolate the effects of cloud changes on SST (both local and non-local) and estimate the hypothetical climatic response to OHT in the absence of cloud feedbacks. Because we are treating the clouds as a forcing rather than a feedback in these calculations, λ in (7) is strictly a clear-sky feedback. It is important to note that with this setup, we cannot analyze the influences that variations in the cloud forcing and the clear-sky feedbacks have on each other.

Fig. 12 shows the forcing terms $H(\phi)$ and $R(\phi)$ (OHT convergence and associated CRE) for a 1 PW increase in OHT, along with the kernel-derived $\lambda(\phi)$. $H(\phi)$ is the same forcing that was applied to our baseline EBM and GCM calculations. Consistent with our discussion in section 3e, the CRE is positive almost everywhere, meaning that cloud changes are working to warm the climate. The equatorial signal is associated with the weakening HC and is relatively insensitive to N. The CRE is largest globally for small N for which the loss of mid-latitude low cloud and the increased greenhouse trapping of polar clouds both play a role.

The clear-sky feedback (Fig. 12c) is negative (i.e., stabilizing) in most locations. We are especially interested in the dependence of $\lambda(\phi)$ on N. If the spatial structure of radiatively important

water vapor change (for example) were highly dependent on the spatial structure of the imposed OHT, this would presumably show up here as variations in $\lambda(\phi)$. Fig. 12c suggests that variations with N as well as with latitude are modest and probably not of leading-order importance in determining the SST response. The large asymmetry between the North and South poles for $N = 5, 6$ can be attributed to noise in the kernel calculation as the change in SST becomes very slightly negative. We will test this assertion in the EBM by comparing two variants of the model: one with the detailed feedback $\lambda(\phi)$, and another with a simple homogeneous feedback $\lambda = -1.45$ W m^{-2} K^{-1}, based on the global average clear-sky feedback diagnosed from the GCM. This is the same constant value used in our baseline EBM.

We also compare two different diffusive parameterizations for the heat transport $F(\phi)$. The classical dry-diffusive model (e.g. North 1975a) sets

$$F_{dry}(\phi) = -K_{dry}\frac{dT}{d\phi} \tag{8}$$

and we use $K = 0.55$ W m^{-2} K^{-1} (our baseline model).

An alternative parameterization crudely incorporates the effects of moisture on the efficiency of atmospheric heat transport:

$$F_{moist}(\phi) = -K_{moist}\frac{d}{d\phi}\left[T\left(1 + f(\phi)\right)\right] \tag{9}$$

where $f(\phi)$ is a moisture amplification factor

$$f(\phi) = \frac{Lr}{c_p}\frac{dq^*}{dT}\bigg|_{T_{ref}(\phi)} \tag{10}$$

with r the near-surface relative humidity and $\frac{dq^*}{dT}$ the rate of change of saturation specific humidity at reference temperature T_{ref}. The parameterization (9) expresses the diffusion of near-surface moist static energy, linearized about the control climate and assuming fixed r (Rose et al. 2014). This parameterization increases the efficiency of diffusion for warm tropical temperatures relative

21

to extra-tropical temperatures. We set $K_{moist} = 0.24$ W m^{-2} K^{-1} for the moist case with 0.8 relative humidity, following Hwang and Frierson (2010) and Rose et al. (2014). K_{dry} is tuned so that the dry model gives the same peak heat transport for a 1 PW increase in OHT with $N = 1$ as the moist model. We will test whether the dry model (8) or the moist model (9) gives a better quantitative fit to the GCM results. Both models are strictly linear, so that responses to $H(\phi)$ and $R(\phi)$ are additive.

The EBM was solved numerically out to equilibrium using the open-source Python package climlab (Rose 2018). Results are plotted in Fig. 13, with the four different model variants in rows and the responses to the two different types of forcing in columns. We also plot the misfit of the EBM solutions to the GCM temperatures. The baseline EBM from section 1 is shown here as the simplest case of no cloud forcing, dry diffusivity, and constant feedback, and is used to validate our numerical EBM solutions against the analytical solution presented in appendix A1.

All EBM variants exhibit tropical cooling and extra-tropical warming in response to increased OHT. The cooling is most pronounced for the most detailed version of the EBM with moist diffusion and local feedbacks. However, the tropical cooling is strongly mitigated by warming from clouds in all cases. This warming effect is tropically-amplified for larger N (the diffusive response to the positive equatorial CRE associated with loss of convective cloud), but polar-amplified for small N (the response to widespread loss of low clouds in the vicinity of the heated region). The combination of the direct effects of OHT and the warming effect from cloud changes results in reduced equator-to-pole SST gradients and tropical thermostat effects, much like in Fig. 3. A version of the EBM in which we impose a global-mean cloud response for each N fails to capture this warming pattern (not shown).

Fig. 13 also shows that meridional structure in the clear-sky feedbacks and the diffusion approximation have surprisingly little effect on the warming pattern. In the tropics, both variables enhance

the cooling associated with OHT divergence and the warming associated with the cloud response, resulting in the negligible net change in SST. The polar amplification for small N is present in all model variants, but is slightly stronger with both moist diffusion and local feedback.

The good quantitative agreement between the EBM and the GCM confirms that cloud changes play the key role in determining the SST response to a change in OHT. Because the cloud forcing varies strongly with N, the mechanisms ultimately driving the warming in the GCM are not universal but depend on the spatial pattern of the OHT.

It is somewhat surprising that the EBM provides such a good fit given that it does not account for changes in wind-driven evaporation. We showed in Fig. 6 that the slowdown of the HC is accompanied by a dramatic decrease in tropical evaporation, and that the resulting large changes in LHF (Fig. 9d) might be critical to the tropical thermostat mechanism. However, convection in the deep tropics strongly couples the tropospheric temperature to the boundary layer and surface below, meaning that the direct SST response to variations in the latent heat flux (i.e., evaporation) are somewhat muted in the climate system (Pierrehumbert 1995).

However, the absence of this effect might still be responsible for the very small negative misfit in EBM temperatures across the tropics for high values of N. Koll and Abbot (2013) shows that the changes in evaporation associated with an increase in OHT result in a slight tropical warming comparable to the misfit in Fig. 13. Also, we have treated cloud changes as an external forcing in the EBM calculation and made no attempt to construct a fully closed model for the effects of increased OHT. It is possible that the climatic impact of reduced evaporation is actually felt most through cloud changes – particularly the sharp reduction in convective clouds at the equator.

5. Discussion and conclusions

We have shown that increased OHT in an aquaplanet climate model is associated with warmer temperatures and weaker equator-to-pole temperature gradients. The warming pattern depends on the meridional structure of the OHT, with global mean surface temperatures increasing slightly more than 2 K per PW transport across $30°$ latitude. The warmer climate is associated with reduced Hadley circulation, reduced equatorial convection, moister subtropics, reduced cloudiness, and partial but incomplete compensation by AHT. Rather than cooling the tropics as might be expected from elementary principles (such as our baseline EBM), increased OHT actually warms the tropics slightly. Both the warming pattern and the hydrological cycle changes differ from those driven by CO_2, suggesting that drivers of past global change might be detectable from combinations of hydroclimate and temperature proxies.

A comprehensive illustration of these various mechanisms is presented in Fig. 14. Increasing OHT out of the tropics results in a partially compensating decrease in AHT. This decrease is accomplished in part via the physical slowdown of the HC, resulting in a decrease in equatorial convection. Decreased convection results in an increase in SW radiation at the surface, offsetting the OHT-driven cooling. In the midlatitudes, surface warming via OHT convergence works to destabilize the lower troposphere and reduce low cloud cover. This in turn increases the SW flux into the surface, further amplifying the midlatitude warming.

Herweijer et al. (2005) and Rose and Ferreira (2013) both attributed the warming from increased OHT primarily to midlatitude moistening. However, we have found that clouds, rather than clear-sky greenhouse processes, play the greatest role in the atmospheric adjustment to increased OHT. We attribute these differences to the relatively simple nature of the GCMs used in the previous studies, particularly with regards to their vertical resolutions. The MITgcm used by Rose and

24

Ferreira (2013) and the GISS model primarily used by Herweijer et al. (2005) had 5 and 8 vertical layers respectively compared to the 26 levels in CAM4. The limited resolution meant fewer degrees of freedom for the models to adjust to the surface forcing, resulting in an atmospheric response dominated by deep convection and the moistening of the upper-troposphere. The higher vertical resolution of the CESM allows for much greater complexity in the low cloud response as well as better coupling of the moist boundary layer to the troposphere.

The meridional SST response to increased OHT simply cannot be captured without knowing the meridional structure of the cloud response. This cloud response in our GCM involves both a reduction in deep tropical clouds (closely tied to circulation changes) and a widespread loss in boundary-layer clouds. The low cloud response in particular is sensitive to the meridional scale of the OHT. Cases for which the convergence is large in the mid-to-high latitudes experience the largest loss of low cloud, and consequently experience the largest warming. This accounts for the approximate scaling of global mean temperature with OHT across $30°$ latitude. Unlike Rose and Ferreira (2013), the warming is not polar-amplified except in cases where OHT reaches into the high latitudes. There is no single universal temperature response pattern governing the climatic response to increased OHT.

The tropical thermostat mechanism can be described as a competition between cooling by OHT divergence and warming by clouds, in agreement with Koll and Abbot (2013). The robustness of this thermostat across all spatial patterns of OHT presents some interesting implications with regards to the warm, equable climate problem presented in the introduction. Even though past OHT patterns are largely unconstrained by proxy data (Bice et al. 2000), this warming mechanism is still viable as the presence of the tropical thermostat does not depend on the forcing pattern. It is a fundamental aspect of the climate response to increased OHT.

The robustness of the Hadley Cell slowdown raises interesting questions about the driving dynamical and thermodynamical mechanisms. Are these mechanisms themselves robust across all N, and how does the HC slowdown relate to compensation in heat transport? These questions, and others surrounding the HC will be addressed in a follow-up study.

These results are robust for both $0°$ and $23.45°$ obliquity patterns. The introduction of seasonality into the model has little influence on the annual-mean response of the HC. It should be noted, however, that the model has weak seasonal temperature cycles due to the 60 m mixed layer depth. There are some differences in the SST response with regards to the amount of polar amplification in the most extreme cases, but they can be attributed to weakened cloud responses at the poles.

It is important to note that these results may be model dependent. While we have shown that there is robustness in the results between the two different obliquity cases within the CAM4 atmospheric GCM, we have yet to test these results using other advanced climate models. Herweijer et al. (2005), Koll and Abbot (2013), and Rose and Ferreira (2013) all look at the effects of increasing the OHT out of the tropics with different AGCMs and produce different results. This can be attributed to the importance of the model water vapor parameterizations and convective schemes to the mechanisms driving the warming. While the warming effects of OHT have been well established, more work is needed to test the robustness of the mechanisms presented in this paper.

Lastly, we acknowledge that these results are limited by the simplified nature of model setup. Global climatic response to OHT variations is mediated in part by sea ice feedbacks and land-sea interactions, yet both are ignored in these simulations. It is therefore useful to think of the warming as a minimum response for an increase in OHT as surface albedo changes will further amplify midlatitude and polar responses. However, there is no evidence that the radiative mechanisms

driving the warming patterns will differ greatly in more realistic simulations. The results presented

are a crucial step in the hierarchical approach to studying OHT effects on the climate system.

<center>APPENDIX</center>

A1. Analytical Solution of the Diffusive EBM

The diffusive EBM (2) is solvable analytically in its simplest configuration with zero CRE, dry

diffusivity and uniform feedback. The steady-state form of the simple model can be written

$$K_{dry}\frac{d}{dx}\left[(1-x^2)\frac{dT}{dx}\right]-|\lambda|T(x)=-H(x) \tag{A1}$$

with $x = \sin\phi$, and where we take the absolute value because of our sign convention $\lambda < 0$. As

discussed by North (1975b), (A1) is a form of Legendre's equation and is solvable so long as the

forcing term $-H(x)$ can be expressed as a series of Legendre polynomials $P_n(x)$.

For any forcing term $A_n P_n(x)$ on the RHS of (A1), there is a solution that satisfies no-flux bound-

ary conditions at the poles:

$$T_n(x)=-\frac{A_n}{|\lambda|}\frac{P_n(x)}{1+n(n+1)\delta} \tag{A2}$$

with the non-dimensional transport efficiency parameter (e.g. Rose et al. 2017)

$$\delta=\frac{K_{dry}}{|\lambda|} \tag{A3}$$

from which we can build a full solution for (A1) by expanding $H(x)$ in a Legendre series.

Here $H(x)$ is the OHT convergence in W m^{-2}. Taking the convergence of (1) and accounting

for the spherical geometry gives

$$H(x)=-\frac{1}{2\pi a^2}\frac{d}{dx}\left[\Psi x(1-x^2)^N\right] \tag{A4}$$

$$=-\frac{\Psi}{2\pi a^2}(1-x^2)^{N-1}\left(1-x^2(1+2N)\right) \tag{A5}$$

<center>27</center>

which is polynomial in x^2 and can thus be expanded in even-order $P_n(x)$:

$$H(x) = \frac{\Psi}{2\pi a^2} \sum_{n=2,4,...,2N} b_n P_n(x) \tag{A6}$$

where

$$\sum_{n=2,4,...,2N} b_n P_n(x) = -(1-x^2)^{N-1}\left(1 - x^2(1+2N)\right) \tag{A7}$$

The coefficients b_n are computed from the expansion formula for even-order Legendre polynomials $P_n(x)$:

$$b_n = (2n+1) \int_0^1 F(x)P_n(x)dx \tag{A8}$$

where

$$F(x) = -(1-x^2)^{N-1}\left(1 - x^2(1+2N)\right) \tag{A9}$$

Expansion coefficients b_n are listed in Table A1 for N from 1 to 8.

The full solution to (A1) is thus

$$T(x) = \frac{\Psi}{2\pi a^2 |\lambda|} \sum_{n=2,4,...,2N} \frac{b_n}{1+n(n+1)\delta} P_n(x) \tag{A10}$$

To use this formula to calculate SST anomalies associated with a given change in OHT, we must recognize that the relevant amplitude Ψ depends on N. The peak OHT occurs at the latitude of zero convergence:

$$x_{max} = \frac{1}{\sqrt{1+2N}} \tag{A11}$$

which we can plug into (1) to get

$$\Psi = \text{OHT}_{max} \frac{(1+2N)^{N+\frac{1}{2}}}{(2N)^N} \tag{A12}$$

Setting $\text{OHT}_{max} = 1$ PW in (A12), substituting in (A10) and using the expansion coefficients in Table A3 then gives a formula for the SST anomaly associated with a 1 PW increase in OHT for a given N in the simple EBM with constant feedbacks and dry diffusion. These solutions are plotted in the top-left panel of Fig. 13 and validate the numerical solver used for the rest of Fig. 13.

28

A2. Evaporation Analysis

Following Lorenz et al. (2010), we analyze changes in evaporation through a simple bulk formula:

$$E = k \left(q^*(T_s) - r q^*(T_a) \right) \tag{A13}$$

where E is evaporation, $q^*(T)$ is the saturation specific humidity, r is the near-surface relative humidity, $k = \rho C |\vec{U}|$ is the turbulent exchange coefficient that depends on wind speed and static stability, and T_s, T_a represent SST and near-surface air temperatures respectively. Taking the fractional derivative with respect to T_a gives

$$\frac{d \ln E}{d T_a} = \alpha - \frac{(1-\gamma)\alpha q^*(T_s)}{q^*(T_s) - r q^*(T_a)} - \frac{\frac{dr}{dT_a} q^*(T_a)}{q^*(T_s) - r q^*(T_a)} + \frac{d \ln k}{d T_a} \tag{A14}$$

$$\frac{d \ln k}{d T_a} = \frac{d \ln(\rho C)}{d T_a} + \frac{d \ln |\vec{U}|}{d T_a} \tag{A15}$$

(equation (9) from Lorenz et al. (2010)), where $\alpha = \frac{1}{q^*} \frac{dq^*}{dT}$ is the CC rate (approximately 7% K^{-1}) and $\gamma = \frac{dT_s}{dT_a}$ is the ratio of changes in SST and near-surface air temperature.

Fig. 6 shows additive contributions to deviations from the CC rate $\frac{d \ln E}{d T_a} - \alpha$ from the second, third and fourth terms on the LHS of (A14). The second term measures the effects of changes in air-sea temperature difference, and is positive if SST warms at a faster rate than T_a (i.e., $\gamma > 1$). The third term measures the effects of near surface relative humidity changes, and is positive if warming is accompanied by a decrease in RH. The fourth term measures the effect of the changes in the turbulent exchange coefficient, and can be further decomposed into changes in near-surface wind speed and static stability through (A15). A decrease in wind speed with warming results tends to suppress evaporation below the CC rate.

A3. Clear-sky and cloudy-sky contributions to greenhouse trapping

Greenhouse trapping G_t as defined in (6) is a number in W m^{-2} that measures the amount by which surface emissions are reduced due to the presence of a longwave-absorbing atmosphere. We can readily calculate changes in G_t after adjustment to some climate forcing in a climate model:

$$\Delta G_t = \Delta F_s^{\uparrow} - \Delta OLR \tag{A16}$$

and this diagnostic has been used in a number of papers (e.g Bony et al. 1997; Herweijer et al. 2005; Barreiro et al. 2011; Rose and Ferreira 2013).

Here we seek the most meaningful way to decompose ΔG_t into cloud and non-cloud effects, a point that has not been addressed clearly in the literature. For any given region with cloud fraction c, the total flux to space is an average of the flux from clear and cloudy sky:

$$OLR = (1-c)OLR^{clear} + cOLR^{cloudy} \tag{A17}$$

so that small changes from a control climate can be conceptually decomposed as

$$\Delta OLR \approx (1-c)\Delta OLR^{clear} + c\Delta OLR^{cloudy} + \Delta c \left(OLR^{cloudy} - OLR^{clear} \right) \tag{A18}$$

and $\Delta F_s^{\uparrow}$ can also be conceptually decomposed into clear-sky and cloudy components:

$$\Delta F_s^{\uparrow} = (1-c)\Delta F_s^{\uparrow} + c\Delta F_s^{\uparrow} \tag{A19}$$

This is useful because $(1-c)\Delta F_s^{\uparrow}$ actually represents the contribution of clear-sky regions to the total change in upwelling flux.

The total trapping change can thus be written

$$\Delta G_t = (1-c)\Delta G_t^{*} + c \left[\Delta F_s^{\uparrow} - \Delta OLR^{cloudy} - \frac{\Delta c}{c} \left(OLR^{cloudy} - OLR^{clear} \right) \right] \tag{A20}$$

where we have defined

$$\Delta G_t^{*} = \Delta F_s^{\uparrow} - \Delta OLR^{clear} \tag{A21}$$

30

which is the change in trapping that would have occurred under completely clear skies, all else being equal.

The first term in (A20), i.e. $(1-c)\Delta G_t^*$, is the actual contribution of clear-sky regions to ΔG_t. The second term is related purely to cloud changes (both absorption changes in cloudy regions and changes in cloud fraction). Thus (A20) gives a natural additive decomposition into clear-sky and cloud processes:

$$\Delta G_t^{clear} = (1-c)\Delta G_t^* \tag{A22}$$

$$\Delta G_t^{cloud} = c\left[\Delta F_s^{\uparrow} - \Delta OLR^{cloudy} - \frac{\Delta c}{c}\left(OLR^{cloudy} - OLR^{clear}\right)\right] \tag{A23}$$

However OLR^{cloudy} is not a quantity that is directly modeled, so (A23) is not useful in this form. On the other hand, GCMs do routinely calculate OLR^{clear} (by making a second pass through the radiation code with the clouds zeroed out), so we can compute ΔG_t^* from (A21). ΔG_t^{cloud} can thus be calculated as a residual using the control climate cloud fraction c. Specifically,

$$\Delta G_t^{cloud} = c\Delta G_t^* + \Delta OLR^{clear} - \Delta OLR \tag{A24}$$

where the sum of the last two terms is also the LW contribution to the change in CRE. We use (A22) and (A24) for our additive decomposition in Fig. 11.

It is important to make the distinction between ΔG_t^*, which measures the trapping the *would* occur *if the same climate change occurred with no clouds present*, from the quantity ΔG_t^{clear} which is scaled by the control clear-sky fraction $(1-c)$, and is thus a more useful measure of *the actual contribution of clear-sky greenhouse processes* to the climate change that occurred.

LIST OF FIGURES

42

FIG. 1. (a) Idealized OHT profiles computed from (1), shown for different values of the meridional scale parameter N and 1 PW peak transport; (b) Convergence of these profiles in W m^{-2} (the prescribed sea-surface heating in our model experiments); (c) SST anomalies for a 1 PW increase in OHT as calculated with our baseline energy balance model (2).
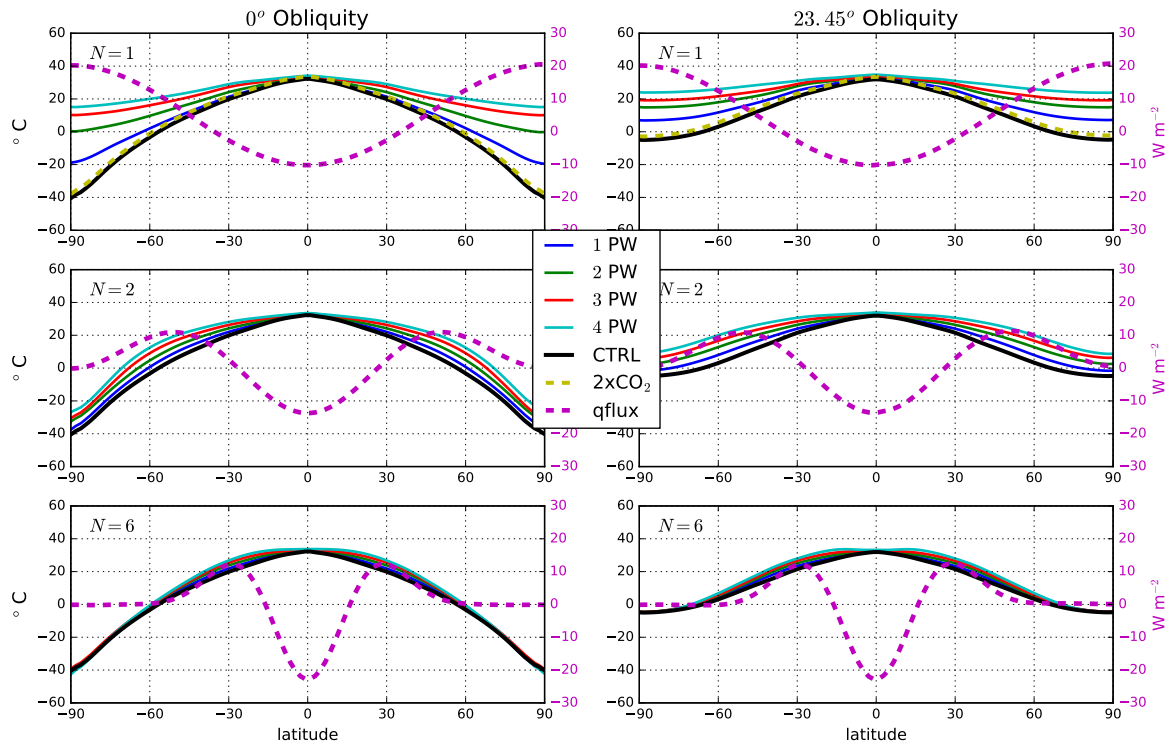

FIG. 2. Zonal, annual mean SST vs latitude as a function of amplitude for $0°$ (left) and $23.45°$ (right) obliquity. Each panel has a fixed meridional scale parameter N as indicated. The dashed magenta lines show the spatial pattern of the q-flux (plotted in W m^{-2} for a 1 PW peak transport). Dashed yellow lines (plotted in the $N = 1$ panels only) show the effects of doubling CO_2 from the zero-OHT control states.
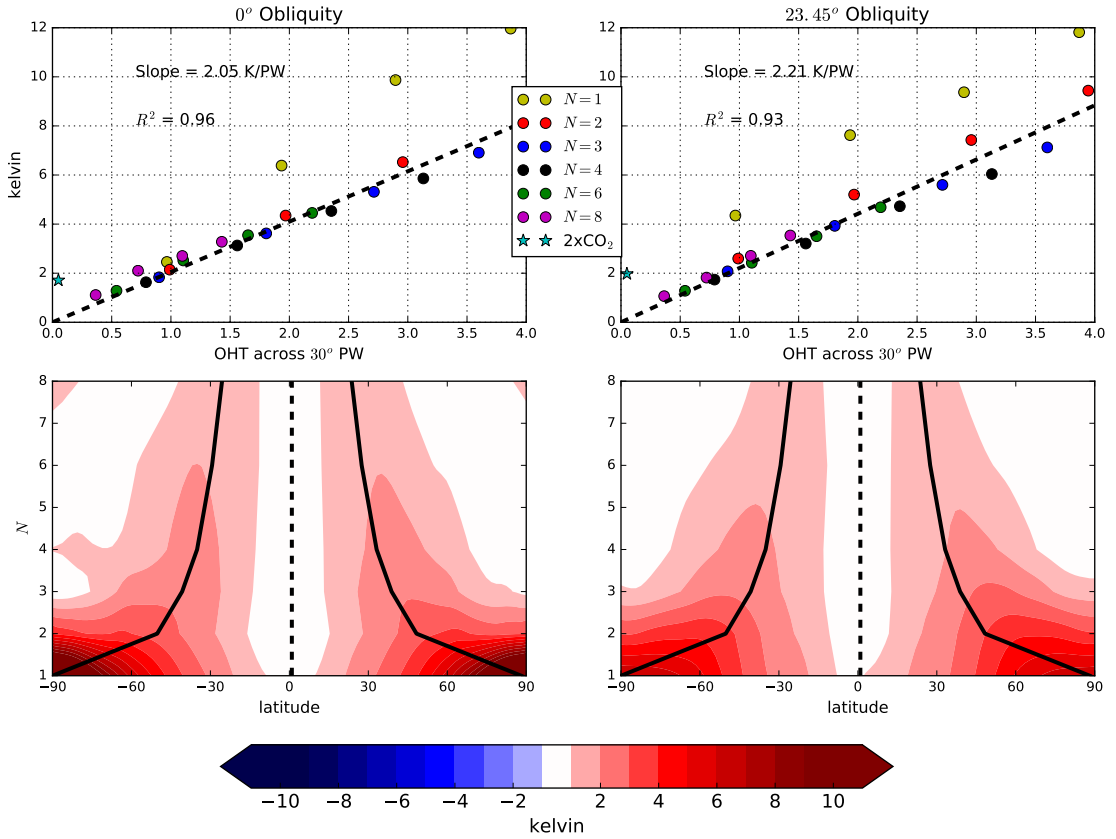

FIG. 3. Global mean SST anomalies with dashed linear best-fit lines (upper) and "spatial anomaly plots" of SST (lower) for the $0°$ obliquity (left) and $23.45°$ obliquity (right) cases. The contoured quantity is the SST anomaly for a 1 PW increase in OHT (from 1 to 2 PW peak transport). Solid and dashed lines show latitudes of maximum OHT convergence and divergence respectively.

45
FIG. 4. Anomalies in SST, insolation (expressed as a meridional transport), and annual-mean SW flux reaching the surface (expressed as a meridional transport) for an obliquity increase from $0°$ to $23.45°$. Global mean warming is 3.13 K.
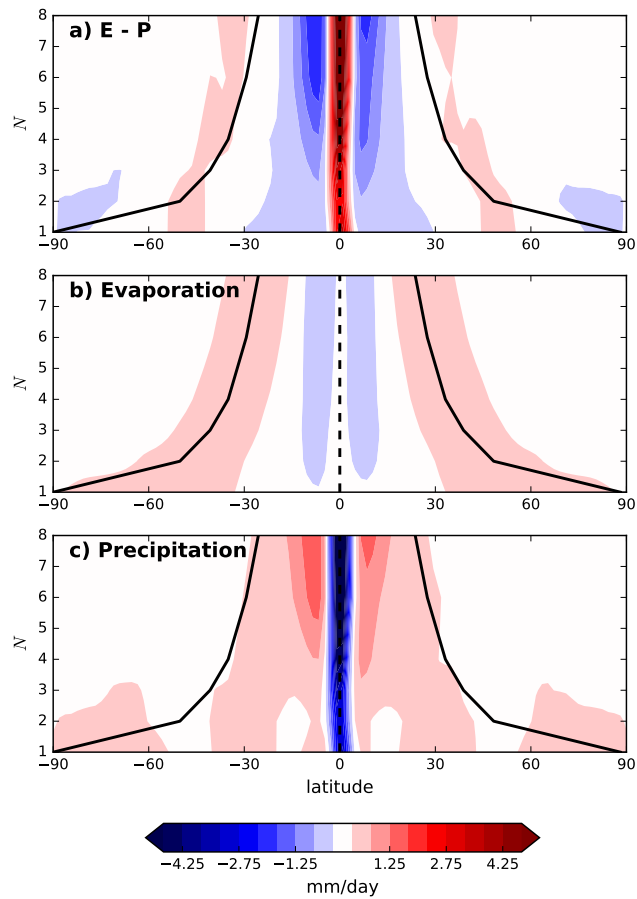

FIG. 5. Spatial anomaly plots (for a 1 PW increase in OHT from 1 to 2 PW, as in Fig. 3, plotted for 0° obliquity only) of (a) E - P, (b) evaporation, and (c) precipitation in mm/day.
FIG. 6. Breakdown of the contributions to surface evaporation anomalies, expressed as deviations of the fractional evaporation changes away from the Clausius-Clapeyron rate (roughly 7%/K) following the method of Lorenz et al. (2010) (left) for doubled CO_2 and (right) a 1 PW increase in OHT for $N = 4$ (plotted for $0°$ obliquity).
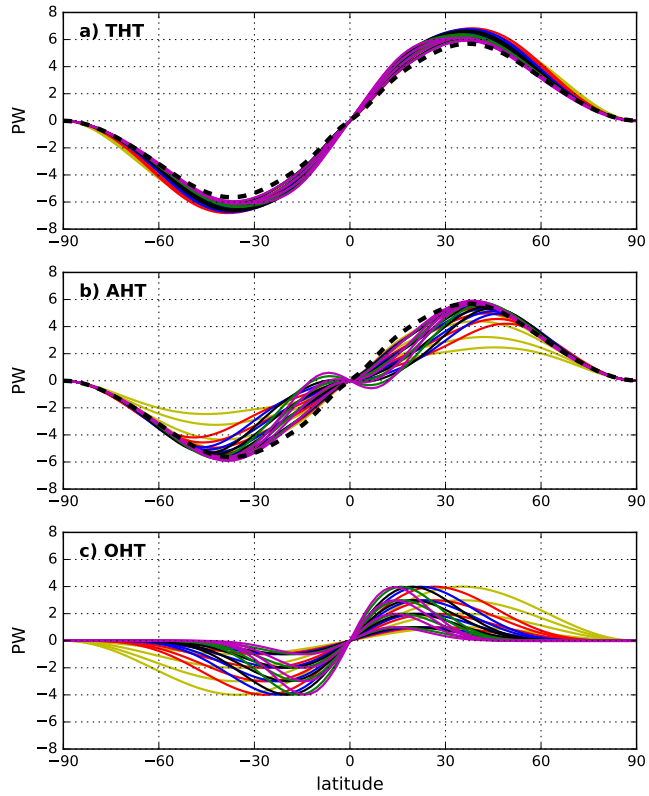

FIG. 7. Zonally averaged (a) THT, (b) AHT, and (c) OHT for all runs with line colors grouped by N. The
dashed black line is the control THT and AHT (plotted for $0°$ obliquity).

49
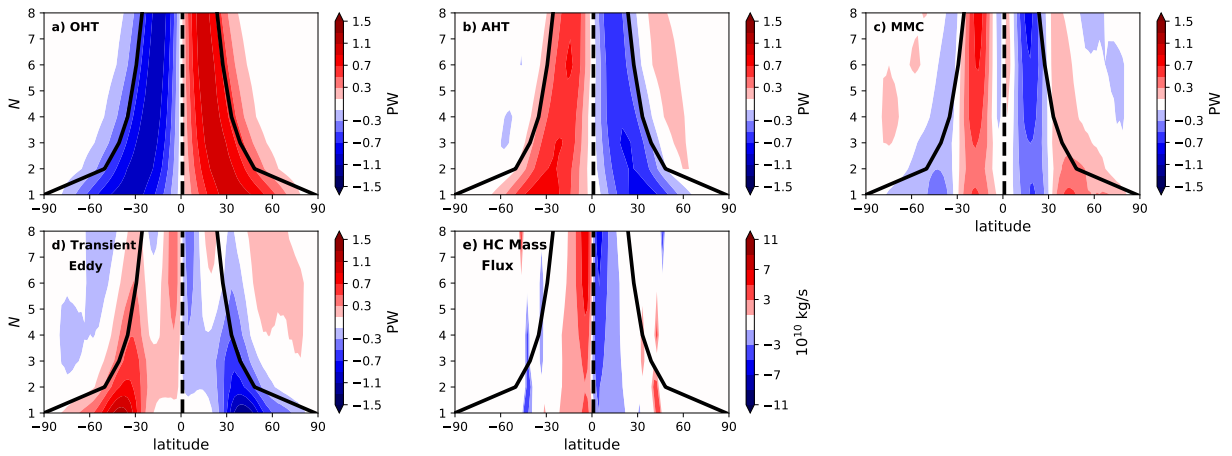

FIG. 8. Spatial anomaly plots (as in Fig. 3, for 0° obliquity only) for (a) total OHT, (b) total AHT, (c) the transient eddy component of AHT, (d) the MMC component of AHT, (e) and the HC mass flux.
FIG. 9. Spatial anomaly plots (as in Fig. 3, for $0°$ obliquity only) of (a) TOA net radiative flux, (b) TOA LW radiative flux, (c) TOA SW radiative flux, and (d) SFC LHF. The sign convention is positive down at TOA (panels (a) through (c)) and positive up at the surface (d).
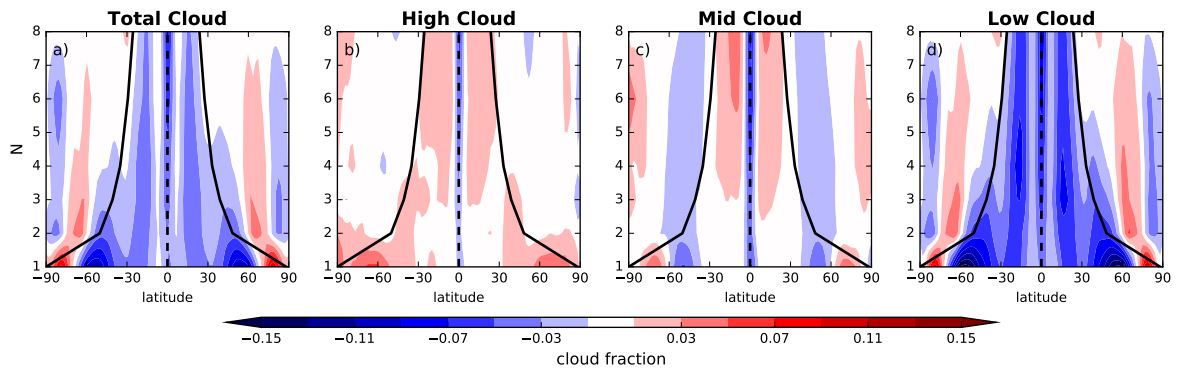

FIG. 10. Cloud fraction anomalies (as in Fig. 3, for 0° obliquity only), vertically integrated for the (a) total atmosphere, (b) high cloud fraction anomalies vertically integrated for cloud top pressures (CTP) less than 440 hPa, (c) mid cloud anomalies vertically integrated for CTP between 680 and 440 hPa, (d) and low cloud anomalies vertically integrated for CTP greater than 680 hPa.
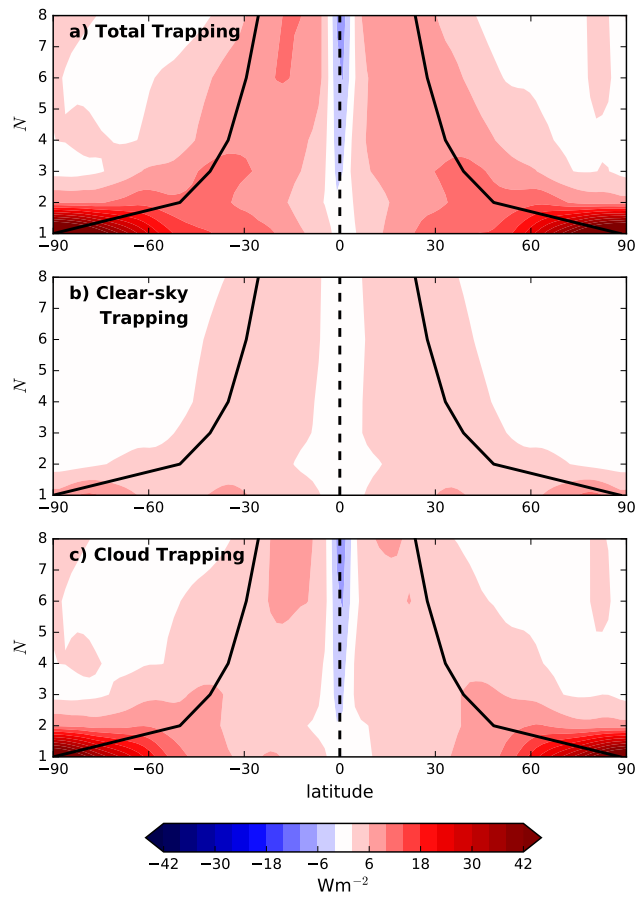

FIG. 11. Anomalies of greenhouse trapping (as in Fig. 3, for 0° obliquity only), decomposed into (a) total, (b) clear-sky, and (c) cloud components.

FIG. 12. Spatial anomaly plots (as in Fig. 3, for 0° obliquity only) of (a) OHT convergence, (b) Cloud Radiative effect, and (c) clear-sky feedbacks.
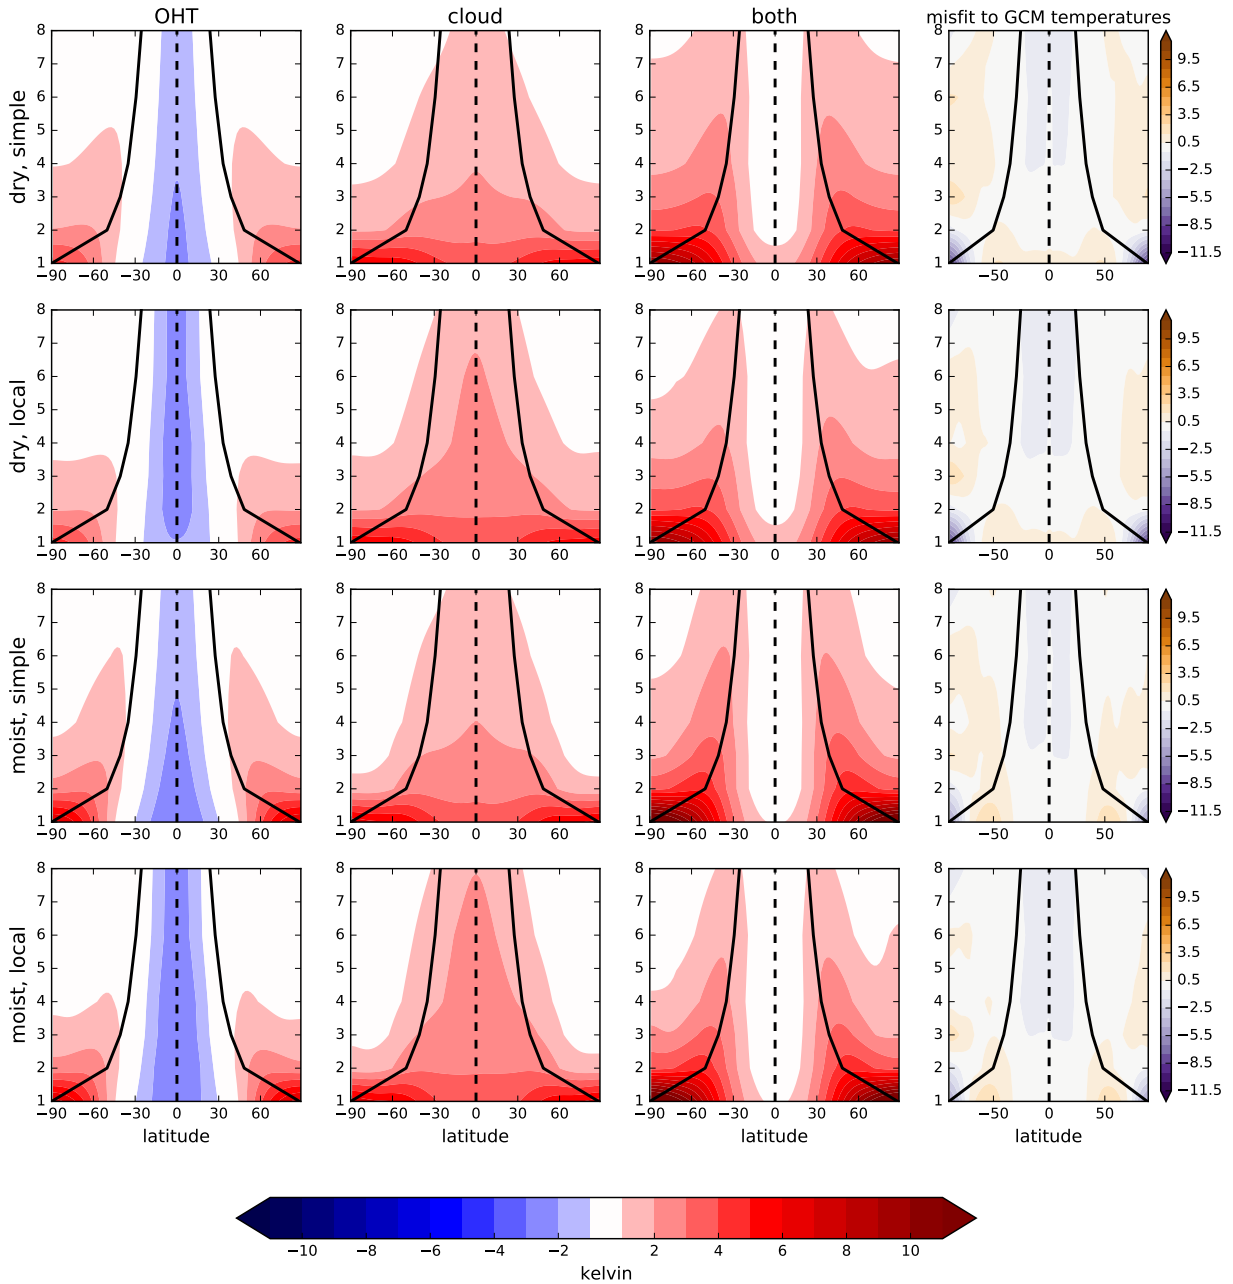

FIG. 13. SST anomalies predicted by the diffusive EBM and comparison to the GCM (at 0° obliquity). Left-most column shows the cloud-free EBM response to a 1 PW increase in OHT (forcing shown in Fig 12a). Second column shows the EBM response to prescribed cloudiness changes as diagnosed from the GCM (Fig 12b). Third column in the response to the combined forcing. Each rows shows solutions for a different set of EBM assumptions – dry or moist diffusion, and constant or local clear-sky feedback, as detailed in the text.
FIG. 14. Schematic representation of the various transport and warming mechanisms associated with a 1 PW increase in OHT for $N = 2$. The blue and green arrows represent the change in OHT and AHT respectively across $30°$. The gray and red dashed lines represent the control and anomalous HC flow respectively. The light red arrows represent area-average changes in net TOA radiation for the tropical and extra-tropical boxes. Oranges arrows are not box-averaged values, but instead represent more localized changes in SW flux associated with key cloud changes at the equator and in the mid-latitudes.
