Abstract. The primary productivity dynamics of the last 200,000 years in the Sulu Sea was reconstructed using the abundance of the coccolithophore Florisphaera profunda in the IMAGES MD97-2141 core. We find that primary productivity was enhanced during glacial periods, which we suggest is due to a stronger East Asian winter monsoon. During the last 80 kyr, eight significant increases in primary productivity (PP) in the Sulu Sea are similar to East Asian winter monsoon changes recorded in Chinese loess. The PP maxima are not linked with Heinrich events (HE) in the North Atlantic, although four PP peaks are synchronous with HE. The PP oscillations have frequencies near those of the Dansgaard–Oeschger cycles in Northern Hemisphere ice records and indicate a teleconnection of the East Asian winter monsoon with Greenland climate. In this Sulu Sea record the East Asian winter monsoon oscillates with periodicities of ~6, 4.2–3.4, 2.3, and 1.5 kyr. In particular, the 1.5 kyr cycle exhibits a strong and pervasive signal from stage 6 to the Holocene without any ice volume modulation. This stationarity suggests that the 1.5 kyr cycle is not driven by some high-latitude forcing.

1. Introduction

The coupling between the atmosphere and the ocean is fundamental to climate dynamics over seasonal to millennial timescales. Variations in this coupling influence the oceanic biosphere and particularly the phytoplankton of the upper ocean layer. In low-latitude areas the phytoplanktonic activity quantified by primary productivity (PP) is correlated to the wind stress dynamics on the sea surface [Nair et al., 1989]. Previous studies have concentrated on long-term changes in the PP [e.g., Beaufort et al., 1997; Mix, 1989], but little is known about the millennial-scale dynamics of PP.

At present, we know that during the last glacial stage our climate system went through rapid changes that are well documented in the North Atlantic area. Two major types of abrupt changes have been described. Heinrich events are documented massive iceberg discharges of ice-rafted debris to the North Atlantic deep-sea sediments occurring with a periodicity of ~6–7 kyr [Bond et al., 1992; Heinrich, 1988]. These events are followed by consecutive abrupt warmings on the Greenland continent. Dansgaard–Oeschger (D–O) climatic oscillations with periods of 1000–3000 years have been described in the Greenland ice cores records [Dansgaard et al., 1993]. These oscillations correspond to ~15°C air temperature shifts between a stadial (cold phase) and an interstadial (warm phase) [Jouzel, 1999].

The Heinrich events are correlative with major changes in the climate dynamics recorded worldwide, from the North Atlantic to the Antarctic. In the Asian region the East Asian winter monsoon strengthened during Heinrich events [Porter and Zhisheng, 1995; Xiao et al., 1999]. Planktonic foraminifera assemblages in South China Sea record these abrupt changes [Chen and Huang, 1998; Wang et al., 1999]. In the Sulu Sea the oxygen isotopes (δ18O) of planktonic foraminifera show important rapid oscillations which appear synchronous with some Heinrich events [Linsley, 1996].

For the Dansgaard–Oeschger oscillations recorded in ice cores, similar changes are documented in sea surface temperature (SST) reconstructions, percentage of carbonate, magnetic susceptibility, planktonic foraminifera oxygen isotopic composition, and foraminiferal assemblage records from the North Atlantic Ocean (for a review, see Cortijo et al. [2000]). The loess-paleosol record in China exhibits comparable shifts [Chen et al., 1997]. In the Santa Barbara basin a bioturbation index records nearly all stadials and interstadials described in the Greenland record [Behl and Kennet, 1996]. At low latitudes, organic carbon changes in the Arabian Sea appear to correlate with D-O cycles [Schulz et al., 1998].

To constrain the past millennial variations of low-latitude paleoproductivity, we investigate, at high-resolution, variations in the coccolith assemblages in IMAGES giant piston core MD97-2141 located in the Sulu Sea (Figure 1).

The Sulu Sea is located between the Asian continent and the “Western Pacific Warm Pool” (WPWP), where annual SST is above 29°C [Yan et al., 1992]. The climate of the Sulu Sea is strongly influenced by the East Asian monsoon. The East Asian monsoon results from the different potential heating between the WPWP and the Asian continent. During the boreal winter the main heating source is located in the ocean. The latent heat release associated with intense convective precipitation fuels the meridional circulation. Tropical convection in the western equatorial Pacific is connected to the descending branch over the Siberian region, forming a strong local Hadley cell in the East Asian region [Zhang et al., 1997]. The East Asian winter monsoon winds in the Sulu Sea result from the merging of the northerly East Asian monsoon with the Pacific trade winds over the South China Sea [McGregor and Nieuwolt, 1998]. East Asian winter monsoon bursts during January to March (Figure 2) can induce blooms of coccolithophors [Wiesner et al., 1996]. The PP rises correlatively to the wind stress strengthening because of the stronger mixing of the upper ocean (Figure 2) [Nair et al., 1989]. Thus coccolith...
assemblages record information on both paleoproductivity changes and also on East Asian winter monsoon variations in the Sulu Sea.

2. Material

The 36 m giant piston core IMAGES MD97-2141 (08°47'N, 121°17'E, 3633 m depth) was retrieved during the IPHIS-IMAGES III cruise of the R/V Marion Dufresne in May 1997. This position is located in the vicinity of the Ocean Drilling Program (ODP) Site 769 [Linsley, 1996]. The core is located on the Cagayan ridge, which protects the site from downslope processes, and above the present lysocline depth (~3800 m), allowing for good preservation of carbonates [Linsley et al., 1985; Miao et al., 1994]. The sediments are composed predominantly of well-preserved nannofossil-foraminifera oozes.

3. Methods

For coccolith counting, the core was sampled every 2 cm in the upper 6 m of the core, allowing for a resolution of ~70 years, and every 3–4 cm in the lower 30 m for a resolution of ~200–500 years. A smear slide was prepared for each sample, and at least 300 coccoliths were counted for each slide (mean of 357 coccoliths) on a Zeiss Axioscop at a 1000× resolution. Percentages of Florisphaera profunda (Fp) were computed using the following equation:

\[
\%Fp = 100\frac{\text{numberFp}}{\text{totalcoccoliths}}
\]

The 95% confidence interval for \%Fp varies between ±2 and ±6% depending on the percentage of Fp [Patterson and Fishbein, 1989].

3.1. Age Model

The age model of the core MD97-2141 was developed by Dannenmann et al. [1998] and Oppo et al. [1998]. It was obtained using 28 accelerator mass spectrometer (AMS) 14C ages on Globigerinoides ruber and G. sacculifer and by comparison of the planktonic foraminifera δ18O curve (on Globigerinoides ruber and G. sacculifer tests) with the SPECMAP stack [Imbrie et al., 1984] (Table 1). The radiocarbon dates were converted to calendar ages using (1) a correction of 400 years, according to the age reservoir of carbon in the ocean [Bard, 1988], and then (2) the CALIB3 calibration software [Stuiver and Reimer, 1993] to take into account past atmospheric changes in cosmogenic production. All the ages discussed here are calendar ages B.P. The carbon reservoir age in this work is assumed to be invariant with time. We also assumed that the carbon reservoir age changes in the tropical upper oceanic layer where G. ruber and G. sacculifer live are not varying more than ~200 years [Duplessy et al., 1991]. The last appearance datum of G. ruber pink at 1593 cm fits with the Termination II [Thompson et al., 1979], strengthening the validity of the age model (Figure 3). Two ninth-order polynomial regressions were used from the core top to 400 cm and from 440 to 920 cm on the 14C ages and SPECMAP tie points to smooth the sedimentation rate for the last 60 kyr. This smoothing is indispensable for the spectral analyses to avoid spurious peaks linked with sedimentation rates changes.
The average sedimentation rate is ~10.5 cm kyr\(^{-1}\), with maxima during glacial stage 2 of 34 cm kyr\(^{-1}\). For example, the sedimentation rate during the stage 3 is ~30 cm kyr\(^{-1}\), which allows a 70 year resolution (2 cm sampling). A hiatus occurs between 30 and 22 ka (Figure 3). The sedimentation rates are coherent with other records; that is, they are increased during glacial periods and lower during interglacial stages [e.g., Chen and Huang, 1998]. Reduced benthic mixing due to dysaerobic conditions in the Sulu Sea lessens the bioturbation smoothing effect [Kuehl et al., 1993]. The sharp transition in the coccolith record at 14.55 ka, occurs within 2 cm, another argument for a weak bioturbation effect.

### 3.2. Signal analysis

#### 3.2.1. Spectral analysis

To extract the significant periodicities contained in the PP signal, we performed spectral analysis using different algorithms (Blackman-Tukey, maximum entropy, and multitaper methods) provided in the package Analysers [Paillard et al., 1996]. The comparison of these different methods allows the discrimination of spurious results due to biases of a particular method. We present only the multitaper method (MTM) results here. The MTM is able to detect low-amplitude oscillations in relatively short time series with a high degree of statistical significance [Thomson, 1982]. The statistical significance reported in this work is computed using a Fisher test (\(F\) test). This \(F\) test is performed on the amplitude to analyze the harmonic oscillations assuming that the signal contains periodic and separated components [Yiou et al., 1997].

#### 3.2.2. Singular-spectrum analysis

Singular-spectrum analysis (SSA) is designed to extract the information contained in a short, nonstationary, and noisy signal [Vautard and Ghil, 1989]. This method is based on the computing of empirical orthogonal functions in the time domain. SSA can give insight into the dynamics of the underlying system that generates the signal. Using data-adaptive filters which are not period dependent, SSA allows the separation of the noise from the trend and the deterministic oscillations of the signal.

### 3.3. *Florisphaera profunda*: A Paleoproductivity Marker

The coccolithophorid (Prymnesiophyceae) are phytoplanktonic organisms that live in the oceanic photic zone. They are very sensitive to variations in light and nutrient availability, which are both depth dependent. The lower photic zone is darker and richer in nutrients than the upper photic zone. In the tropical ocean the lower photic zone coccolithophorid community is dominated by *Florisphaera profunda* associated with *Gladiolithus flabelletus* and *Algirosphaera robusta*, while most of the other species live in the upper photic zone [Okada and Honjo, 1973].

When the nutricline is shallow, the upper photic zone species dominate the coccolith community, whereas when the nutricline is deeper, the relative proportion of lower photic community is more important. The depth of the nutricline in the low-latitude open ocean is mainly driven by wind intensity. When winds are strong, the upper layers are well mixed, and the nutrients are upwelled into the upper photic zone. Inversely, when wind stress decreases, the mixing is less effective, and the photic zone is depleted in nutrients. This depth relationship between coccolithophorid communities was successfully used by Molfino and McIntyre [1990] to monitor changes in the nutricline depth and has been calibrated to primary productivity by Beaufort et al. [1997] for paleopродuctivity reconstructions.

The relationship between the *Florisphaera profunda* ratio and primary production has already been quantified by Beaufort et al. [1997] with the following equation:

\[
y = 617 \times [279 \log(x + 3)],
\]

where \(y\) is the yearly PP (g C m\(^{-2}\) yr\(^{-1}\)) and \(x\) is the percent Fp. This equation is based on Indian Ocean low-latitude core tops. We assume the coccolithophorids’ assemblage distributions are homogeneous in the intertropical zone. The variations of Fp are in agreement with other paleoproduction proxies [Beaufort et al., 1997].

### 4. Results

The present annual PP in the Sulu Sea is 148 g C m\(^{-2}\) yr\(^{-1}\) [Antoine and Morel, 1996], which is close to the average reconstructed PP over the last 200 kyr of 135 g C m\(^{-2}\) yr\(^{-1}\). The PP (data are accessible at http://www.cerege.fr and at ftp://ftp.noda.ngdc.gov/paleo) oscillates during the last 200 kyr between 81 and 223 g C m\(^{-2}\) yr\(^{-1}\) (Figure 3).

#### 4.1. Glacial-Interglacial Variations

On a glacial-interglacial timescale, PP increases during glacial periods and decreases during interglacials (Figure 3). PP is moderately correlated \((r^2 = 0.49)\) with the ice volume curve (SPEC-MAP stack of Imbrie et al. [1984]). This is shown by the spectral analysis of the paleoproduction record, which contains orbital frequency peaks of Milankovitch theory (i.e., 1/100 kyr, 1/41 kyr, and ~1/20 kyr) (Figure 4) and confirmed by cross-spectral analysis between the PP and the SPEC-MAP stack (not shown). This orbital forcing explains about half of the variance of the PP record. Half of
4. Sub-Milankovitch Dynamics

4.2.1. Bolling/Allerod and the Younger Dryas event. The last deglaciation is marked by the Younger Dryas event, which interrupts the global warming trend in the Northern Hemisphere. The Younger Dryas seems to be at least hemispheric in extent and is still controversial. Two main hypotheses were summarized by Anderson and Thunell [1993]: either it reflects a cooling event or it is due to a change in the sub-Milankovitch timescale.

The interpretation of the Younger Dryas event in the Sulu Sea is still controversial. Two main hypotheses were summarized by Anderson and Thunell [1993]: either it reflects a cooling event or it is due to a change in the sub-Milankovitch timescale.

The variance of the PP time series remains to be explored in the sub-Milankovitch timescale.

See Dannenmann et al. [1998] and Oppo et al. [1998].

Error is given in 1σ.

Calendar ages have been calculated using a 400 year reservoir correction and applying the Stuiver and Braziunas [1993] calibration curve for samples younger than 20,000 calendar year in age and a U/Th calibration curve for the samples older than 20,000 calendar years [Bard et al., 1993].
et al., 1991) or an atmospheric variation [Anderson and Thunell, 1993].

The PP plateau during the Allerod and the Younger Dryas is similar to the warming recorded by alkenones records from the cores 17961 and 17964 in the South China Sea (SCS) [Pelejero et al., 1999a, 1999b]. The Younger Dryas–Allerod SST difference in the SCS is 0.4°C. This corresponds to an increase of ~0.1% of the foraminiferal δ18O, 20% of the 0.5% change observed in Sulu Sea sediments [Linsley, 1996]. Our PP record strengthens the argument that East Asian winter monsoon dynamics during Younger Dryas were not significantly different from the Allerod because of the small measured change in the PP record between the Allerod and the Younger Dryas. Thus the change in planktonic foraminifera δ18O composition in the Sulu Sea between the Allerod and the Younger Dryas seems to be mainly due to an isotopic variation in ocean water linked to salinity, after a major change in atmospheric processes 14.5 kyr ago, during the Bolling.

4.2.2. Millennial-scale PP events during MIS 3. The Heinrich events in the North Atlantic have been correlated to short increases of the East Asian winter monsoon dynamics [Chen et al., 1997; Porter and Zhisheng, 1995]. In order to compare the millennial variations in the North Atlantic and the PP variations in the Sulu Sea we smoothed the PP record with a 2 kyr average moving window and resampled at a 100 year time step (Figure 5). This 2 kyr window keeps only the variance at the millennial and longer timescales and attenuates the century-scale variations. During the last 80 kyr the PP record reveals eight events numbered PP1-PP8, some of which may be synchronous with North Atlantic environmental changes (Figure 5). The first one (PP1) at ~8.3 kyr ago is in phase with the early to middle Holocene transition period [Alley et al., 1997]. PP2 matches with Heinrich Event 1 (HE1). PP3 occurs during the Last Glacial Maximum. PP4 seems to correlate with HE4. PP5 and PP6 do not match with any major Heinrich Events, and HE5 is being intercalated between these two PP increases. However, PP5, at ~44 ka is correlated to an increase of the winter monsoon strength recorded in paleofoos from China, dated between 43.3 and 45.2 kyr BP (PL7 of Chen et al. [1997]). PP7 could be related to HE6. PP8 does not match any Heinrich Event. Chen et al. [1997] also describe two events at 59.2–66.2 ka (PL9) and 68.6–71.2 ka (PL10), which may correlate with PP7 and PP8 given age model uncertainties. In conclusion, all PP maxima in the Sulu Sea can be correlated with Chinese loess events and notably events PP5 and PP8 may correspond only with the Chinese loess record. Therefore we conclude that these regional

Figure 3. Note the hiatus between 400 and 440 cm (shaded area). (b) MD97-2141 δ18O planktonic foraminifera results at 10 cm intervals (shaded line) compared with the SPECMAP stacked deep-ocean record (thick solid line). (c) MD97-2141 primary productivity (PP) as reconstructed from the coccolithophorid record.
events are indicative of significant changes in the East Asian winter monsoon dynamics. PP1, PP2, PP4, and PP7 match clearly with North Atlantic Heinrich Events. In stage 3, uncertainties in the age model that cannot be smaller than ±2 kyr may explain the relative discrepancy between PP5 or PP6 and HE5 but cannot account for the occurrence of supplementary peaks (PP5 or PP6 and PP8). Our data indicate that the dynamics of the East Asian winter monsoon is not directly linked with the major iceberg discharges in the North Atlantic as stated by Porter and Zhisheng [1995]. The East Asian winter monsoon exhibits higher-frequency dynamics than that of the main HE. However, it remains to be determined if a common dynamic is present between the high- and the low-latitude records that is not linked with major icebergs discharges. We next compare the Dansgaard–Oeschger cycles recorded in the Greenland ice core records with our PP record from the Sulu Sea.

To evaluate Dansgaard–Oeschger scale variability, we performed SSA on the Sulu Sea PP and on the GRIP δ18O records to examine the relationships between Greenland climate and East Asian winter monsoon dynamics. For this analysis, we resampled the two records at 200 year time intervals after interpolation. We computed SSA with the Vautard-Ghil autocovariance estimator embedded in 20 dimensions corresponding to 2000 years. The first principal component (PC) in the two records describes the long-term trend, and the second PC shows millennial dynamics (Figure 6 and Table 2). There is a good agreement between the two PC2 records of millennial dynamics in PP and temperature in Greenland during the last 70 kyr. PP increases in the Sulu Sea when temperatures in Greenland decrease. Cross-spectral analysis indicates high coherency between the PC2 of PP and the PC2 of GRIP for the ~6 and 3.5 kyr frequency bands with phases of ~160° and of 140°, which is indicative of the opposite phase described above. This phase relationship is well constrained for the deglaciation by 13C ages. The phase cannot be further investigated because of limited synchronization between the ice core records and the marine records inherent to differences in established chronologies.

A strengthening of the East Asian winter monsoon during the glacial stages is compatible with the conclusions of several studies already carried out in this area [Chen and Huang, 1998; Wang et al., 1999]. It corresponds to a strengthening of the Hadley cell between the Western Pacific Warm Pool Low and the Siberian High. This mode of atmospheric circulation is compatible with last glacial stage simulations [Kutzbach et al., 1993]. The Siberian Highs are directly connected to the Ferrel cells, which influence the Greenland and Asian climates. This teleconnection should operate via the coupling of these two cells (Ferrel and Hadley) during the winter.

In conclusion, the lack of a systematic correlation between the Sulu Sea PP and HE indicates that iceberg discharges in the North Atlantic and the East Asian winter monsoon follow different dynamics. However, the correlation between the Greenland climate PC2 and the East Asian winter monsoon PC2 indicates that similar millennial-scale climate variability affects both the Greenland and the Western Pacific climates.

4.3. Analysis in the Frequency Domain (Suborbital Frequencies)

Three time slices were defined to explore high-frequency cycles in the PP record. The first one, from 22 to 4.1 ka, spans the whole deglaciation. The second one, from 60 to 30 ka, includes most of stage 3. The third one, from 160 to 130 ka, corresponds to the end of stage 6. The PP records were detrended in each segment using a ninth-order polynomial for the deglaciation, a fourth-order polynomial for stage 6, and a linear detrend for stage 3 (Figure 7c). The three records show variance peaks at periods of ~6, 3.5, and 2.4 kyr and between 1780 and 1200 years with a mean at 1500 years (Figure 7e–7g). The spectral peaks could be related to the age...
model. However, changing the age model from polynomial fits to linear fits does not change the periods of the peaks >100 years, and the relative timing of the peaks is kept. Thus the spectral peaks seem to be robust features of the signal with this current age model.

4.3.1. The $\approx 1.5$ kyr cycle. For the time slice from 4.1 to 22 ka the most significant peak occurs at 1.38 kyr (significance of 93%). In the 30–60 ka time slice, two peaks occur at 1.54 kyr (98.5%) and 1.2 kyr (99.8%). In the last time slice the peak at 1.48 ka (99%) is the strongest. The strongest periods are all around 1.4–1.5 kyr, and the occurrence in three different time-slices indicates probably a common origin and an almost stationary signal across different climatic conditions.

4.3.2. The $\approx 2.4$ kyr cycle. In the 4.1–22 ka time slice, two minor peaks occur (2.58 and 2.17 kyr), but they are not significant. In the 30–60 ka time slice the prominent peak occurs at 2.32 kyr (significance of 79.8%). In the 130–160 ka time slice a significant peak is at 2.43 kyr (96%). The period of 2.4 kyr seems also stationary, but its strength varies through time. It is more marked during the glacial stages and may correspond to ice volume forcing.

4.3.3. The $\approx 4.2-3.3$ kyr cycle. In the time slice from 22 to 4.1 ka the peak is at $\approx 4.2$ (significance of 97%). The 30–60 ka time slice peaks at 3.6 kyr (97%), and in the 130–160 ka time slice the significant peak is at 3.36 kyr (86%). The strength of this peak is strong in all the time slices, but the period does not seem to be stationary.

4.3.4. The $\approx 6$ kyr cycle. In the time slice between 4.1 and 22 ka the peak at $\approx 8$ kyr is not significant because of the dominant deglaciation signal overprints on the low-frequency band. In the 30–60 ka time slice a peak occurs at 5.7 kyr (significance of 89.9%), and between 130 and 160 ka the significant peak is at 6.7 kyr (92.1%) with another concentration of variance at $\approx 5.06$ kyr (90.5%). This frequency is most pronounced during the glacial periods.

5. Discussion: High-Frequency Cycles

Because the frequency of $\approx 6$ kyr$^{-1}$ is close to the Heinrich Events’ frequency band, we filtered the PP record in this frequency band using a Gaussian filter (bandwidth of 0.1666 kyr$^{-1}$). The resulting PP series clearly shows an amplification during the glacial periods, with minima during interglacials (i.e., Holocene and stage 5: 75–130 ka), and indicates that this frequency seems to be ice volume forced. The amplification could depend on the high-latitude ice volume available for ice rafting events.

A 3.7 kyr cycle has already been reported by Pestiaux et al. [1988] in the Indian Ocean. A similar periodicity of 3.3 kyr was also reported by Sirocko et al. [1996] in a production record from the Arabian Sea. These authors attributed this frequency band to combination tones of orbital forcing on monsoon dynamics. In the Sulu Sea this period is significant during the MIS3. This period is not very stable in the PP record, oscillating between 3.62 kyr for stage 3 and 3.36 kyr for stage 6. The identification of this period in several paleomonsoon records seems to indicate that this period is significant in Asian monsoon system dynamics. The hypothesis of combination tones related to precessional and to obliquity frequencies, which forces the climate system like a nonlinear oscillator [Pestiaux et al., 1988], could explain the variations of the spectral peaks contained in this frequency band. Even if a nonlinear climatic oscillator predicts only periods $>5$ kyr, the monsoon system by its amplification of insolation forcing could probably generate cycles in this frequency band [Pestiaux et al., 1988].

5.1. The 2.4 kyr Cycle

The PP exhibits a strong 2.4 kyr cycle, especially during the last two glacial stages (MIS 2–3 and 6). This period has already been described in oceanic sediments. Pestiaux et al. [1988] observe a 2.3 kyr period in the Indian Ocean hydrography, which
was interpreted as a combination tone of the precessional and obliquity cycles, representing an internal but nonlinear response of the monsoon system to solar forcing. This cycle is also present in the atmospheric $^{14}$C excess record [Stuiver and Braziunas, 1993], which depends on the solar flux (Hallstattzeit cycle [Damon and Jirikowic, 1992]) and on the oceanic-atmosphere exchange of $^{14}$C. A 2.2 kyr periodicity was also reported in a monsoon record from the Oman margin [Naidu and Malgrem, 80]

which was attributed to interactions between oceanic circulation changes and atmospheric $^{14}$C changes at a 2.3 kyr period. This cycle is not expressed in Termination I of the Sulu Sea PP record. However, it is significant for the glacial stages.

The low expression of this cycle in the Sulu Sea during the last termination is perhaps due to the strong overprint of the 1.5 kyr cycle on the PP record. This cycle seems to be stationary throughout this record.

Figure 7. (a) MD97-2141 primary productivity (0–200 ka). Three intervals are enlarged in Figures 7a–7c. (b) From 4 to 22 calendar kyr B.P. A polynomial of third order (thin solid line) was applied to detrend the primary productivity signal (thick solid line) before the multitaper method (MTM) spectral analysis. (c) From 35 to 60 ka. PP (thick solid line) is represented, a linear detrend was performed before spectral analysis. (d) From 130 to 160 ka. A fifth-order polynomial (thin solid line) of the PP (thick solid line) was also subtracted from the PP record before the spectral analysis. (e–g) MTM spectra of the three time windows in Figures 7b, 7c, and 7d, respectively. Line amplitudes (dashed line) and $F$ test (estimate of confidence; solid line) are plotted versus period. The shaded areas represent significant frequency bands.
5.2. Pseudo 1.5 kyr Cyclicity

A 1.47 kyr period was first described by Dansgaard et al. [1984] in the Camp century $\delta^{18}O$ ice core record. In the Summit ice core (GISP2) the $\delta^{18}O$ and the polar component of a principal component analysis computed on various chemical markers in the ice both show periods ~1.5 kyr [Mayewski et al., 1997]. A 1.47 kyr period was also described by Bond et al. [1997] in North Atlantic deep-sea cores during the Holocene and the deglaciation. In Alaska, a lake record contains climatic variations with a 1.5 kyr cycle [Campbell et al., 1998]. These records provide growing evidence for cyclicity of ~1.5 kyr in many high-latitude records. This cycle was also recently linked to fluctuations in continental ice mass during periods of lowered sea level (~45 m below present level) by a simple model of ice dynamics [Schulz et al., 1999]. At lower latitudes the southwest Indian monsoon also shows clear 1.45 kyr cycles in a paleoproductivity record spanning the last deglaciation [Sirocko et al., 1996]. Sirocko et al. speculate that this relationship could be due to subpreeconomic forcing.

In the Sulu Sea the primary productivity shows clear peaks in a broader 1.5 kyr band (Figure 7). The peak in PP is at 1.38 kyr for the last 22 kyr. For stage 2–3 the major peak is at 1.37 kyr. That ~1.5 kyr cyclicity is also present during stage 6. During the last deglaciation the cycles are well defined. This pseudoperiodicity appears significant in the three time slices, suggesting that it is a pervasive feature of the East Asian winter monsoon dynamics. Our low-latitude record clearly does not record an amplification with increase in the polar continental ice masses (i.e., the sea level does not modulate the envelope of the 1.5 kyr cycle). During the last 160 kyr, eight maxima in the 1.5 kyr envelope were counted, which correspond roughly to the precession period (160/8 = 20 kyr) (Figure 8b). The East Asian monsoon 1.5 kyr cycle Thus could be the climatic expression of a combination tone of the orbital insolation frequencies as already expressed by Pestiart et al. [1988] and Sirocko et al. [1996]. The pervasive occurrence of this cycle during both glacial and interglacial periods in the subtropics seems to indicate that if a 1.5 kyr climate oscillator exists, a common origin between high and low latitudes is expected for this cyclcity. We suggest that its presence in the Sulu Sea is not forced by high latitudes, as indicated by its presence during stages 1 and 5 in the Sulu Sea and absence in the intervals in the GRIP record [Stuiver and Braziunas, 1993]. Further data are necessary to improve the definition of the frequency bands and the geographical extent of these rapid climate cycles.

6. Conclusions

We reconstructed primary productivity (PP) from coccoliths in the MD97-2141 core, located in the Sulu Sea during the last 200 kyr.

1. We find that PP increased during the glacial stages, whereas the interglacials are times of lower PP. We attribute this PP change to a strengthening of the East Asian winter monsoon in the Sulu Sea during glacial stages.

2. The PP record indicates that an abrupt decrease in the East Asian winter monsoon occurred 14.55 calendar kyr B.P., followed by a ~2 kyr plateau during both Allerod and Younger Dryas. It shows that changes in the $\delta^{18}O$ record from the Sulu Sea during the Younger Dryas are most likely linked with sea surface salinities changes.

3. The PP record exhibits eight rapid oscillations during the last 70 kyr. Only four PP events are synchronous with Heinrich Events. This implies that the East Asian winter monsoon and North Atlantic iceberg discharges follow different dynamics, and that HE are not systematically forcing increases in the East Asian winter monsoon. However, these PP oscillations appear to correlate with peaks of the East Asian monsoon recorded in the Chinese loess. In the timescale close of the pacing of Dansgaard–Oeschger cycles, singular-spectrum analysis reveals that the PP record in the Sulu Sea can be correlated with the Greenland climate. Therefore a common dynamic, which is not forced by icebergs discharges in the North Atlantic, is present in both high- and low-latitude paleoclimatic records.

4. Four dominant frequencies were isolated in the high-frequency pacing of the East Asian winter monsoon. They occur (1) at ~6 kyr, (2) in a 3.3–4.2 kyr frequency band of unknown origin, (3) in a 2.4 kyr frequency band probably resulting from the coupling between solar flux and oceanic processes, and (4) in a 1.5 kyr band. This ~1.5 kyr pseudoperiodicity is a pervasive feature of the East Asian winter monsoon during the marine stages 1, 3, 5, and 6. The origin of this climatic cyclicity remains unknown, but we suggest that its presence at this site in the low-latitude western Pacific is not forced from the high latitudes.

Acknowledgments. The support of French MENRT, TAAF, CNRS/INSU, and IFRTP to the Marion-Dufresne and the IMAGES Program was necessary to perform this work. T.G. was supported by a predoctoral grant of the French Ministère de la Recherche. Financial support from INSU grant to T.G. and L.B. is acknowledged. B.K.L. acknowledges grant OCE 9710156 and technical assistant Stephen Howe. We are indebted to Delia Oppo, who contributed to the collection of the AMS $^{14}C$ ages at the WHOI-NOSAMS AMS facility and $\delta^{18}O$ data with the NSF grant OCE-9710097, and the technical help of Susan Trimarchi and Luping Zou.
